spective and an evaluation is made of the place that any lay concepts may be hoped to assume within the theory of attribution.

The Cause–Reason Distinction Reconceptualized

Some Problems With Current Conceptions of Cause Versus Reason

Let us see how Buss characterizes *cause*, *reason*, and the differences that set them apart. As he expressed it (Buss, 1978, p. 1311), "causes are that which brings about a change," whereas "reasons are that for which a change is brought about (e.g., goals, purposes, etc.)." In Aristotle's classification, Buss's *cause* is *efficient cause*, *reason* is *final cause*, and they are both presumed to differ from *material cause*, or "that in which the change comes about," and *formal cause*, or "the pattern or shape of that which is changed" (p. 1312). We are further informed that causal explanation is associated with "such connotative 'attributes' as lawfulness, determinism, antecedent–consequent relationship, predictability and replicability" (p. 1314).

But the foregoing clarifications notwithstanding, the distinction between *cause* and *reason* still seems possessed of a "will-o'-the-wisp" quality. For instance, characterization of *cause* as "that which brings about change" would appear equally applicable to reason. Surely an actor has a reason for an action before it occurs (a person may feel thirsty and then proceed to drink), and action would not have occurred without the reason, so the reason may well be said to bring about the change (i.e., the action). This conclusion is hardly altered if *reason* is conceptualized as the end state that the actor strives to attain (e.g., the quenching of one's thirst). Anticipation of the end state must antedate the action and, in a sense, bring it about. Needless to say, the actual end state (vs. mere anticipation thereof) does not bring about the action, and many a behavior may run its course without eventual attainment of the underlying purpose.

The above considerations suggest that reason may bring about action (change) and that the antecedent–consequent relation that Buss (p. 1314) reserved for causal explanation is shared by teleological explanation. Furthermore, it appears that lawfulness, predictability, replicability, and even a certain sense of determinism may well be predicated on teleological explanations, so they may not differentiate it from causal explanation. To explain a person's action in terms of a reason means that, all else being constant, given the reason, the action would follow. This of course means that reason and action are *lawfully* (hence *replicably*) related and that action may be *predicted* from reason. As has just been noted, actual success in predicting an action from a reason requires the *constancy* of all remaining conditions including possible alternative goals and beliefs that the actor might have as to the best means for accomplishing his/her particular end. That such psychological constancy across occasions might sometimes be unlikely *in practice* does not in the least detract from the *principle* of predictability and replicability intended by teleological explanation.

To illustrate the essential lawfulness conveyed by a teleological explanation, consider a brigand accosting a victim with a "money or life" dilemma. Most people would agree that the brigand is attempting to elicit in the victim the "life-saving" end as well as the belief that yielding the money would be the surest way of reaching this end. Note that the brigand's expectation of being obeyed (or this person's prediction that he/she would be) betrays the assumption that purposes systematically lead to actions (that may best serve the purposes involved).

Furthermore, should the brigand's prediction fail to materialize (should the victim refuse to comply), it seems unlikely that this would be explained by an unlawfulness of the purpose–action relation. Rather, the actor's unexpected behavior would probably be taken to reflect a shift in circumstances, that is, a violation of the constancy assumption, that may render the situation irrelevant to the original purpose–action hypothesis. For example, one might postulate that a different purpose dominated the victim's conduct (a

sudden penchant for heroics) or that the actor deemed a different action to serve the original purpose best (having become a black belt in karate, the victim could feel that a side kick to the assailant's chin might best rid him/her of the threat involved).

Thus, contrary to implying that the relation of purpose to action is helter-skelter, social interaction seems fundamentally to depend on a belief that the latter may be predicted from the former, that is, to depend on the essential lawfulness intended by teleological explanation (for a similar view see, e.g., Schlenker, 1974). The preceding discussion makes plain that the demarcation of teleological explanation from causal explanation is a largely unaccomplished task.

An Asymmetrical View of Cause Versus Reason

I believe that the cause–reason question may be neatly resolved (or dissolved) when reformulated *asymmetrically* rather than *symmetrically*, as it has been formulated by several contemporary commentators (e.g., Buss, 1978). By a symmetrical interpretation of cause versus reason I mean their treatment as equally definitive concepts of unique significance for the problem of explanation. However, while most people seem to have little difficulty with the concept of reason (usually defined in such familiar terms as purpose or goal), explication of the notion of cause has required considerable analytic efforts. For example, Buss approvingly cites the view that "causal explanation of human action would be in terms of bodily movements" (Buss, 1978, p. 1313). In addition, Buss equates causality with "that which makes things happen, or brings about change" (p. 1312). I admit to finding such clarifications not entirely satisfactory and to being left with a gnawing sense of ignorance regarding the intended meaning of cause as a concept.

According to the present asymmetrical view, reason is interpreted as a specific type of explanation (notably, teleological), whereas cause is interpreted as explanation[1] in the generic sense. More precisely, the cause notion has apparently been employed in two broad senses: one sense (henceforth labeled *inclusive*) has denoted any explanation, including the teleological. The second sense (henceforth *exclusive* has denoted any explanation excluding the teleological. The inclusive sense seems to underlie Aristotle's classification of causes into efficient, material, formal, and final, for example. This line of reasoning seems now to reflect simply four types of explanation, of which teleological explanation (based on final causes) may be one. Similarly, in attribution theory, frequent references to causal explanation connote (somewhat redundantly) the theory's concern with naive explanation of whichever type rather than with special kinds of naive explanation. Finally, the pervasive use of the because preposition with all types of explanation is readily comprehensible if we assume that cause simply means explanation, no more, no less.

The exclusive interpretation of cause (as any nonteleological explanation) seems prominent in those treatments where it is explicitly opposed to reason, as in Buss's (1978) recent analysis. In those instances, cause seems defined negatively as a "nonreason" but is not further characterized more positively. In the remainder of this article, too, cause will be contrasted with reason and will exclusively denote any nonreason-type explanatory category. Regardless of whether the inclusive or the exclusive view of cause is adopted, the assymmetrical interpretation of the cause–reason issue has this fundamental implication: Reason is merely one type of explanation, whereas cause may include an infinite variety of explanatory types. Thus Aristotle's fourfold classification of possible causes is considered a wholly arbitrary taxonomy. Besides efficient, material, formal, and final explanations, one can have mathematical, mechanical, geographic, demographic, or social explanations,

---

[1] Consistent with common usage, *explanation* is used here to mean a statement constructed around the connective *because* (as in "Bill stayed home because it rained"). It is generally accepted that such statements presume a universal conditional (if–then) proposition ("if it rains Bill stays home") and an instantiating clause affirming the antecedent of the above conditional ("it did rain"; see, e.g., Popper, 1961, p. 19; Turner, 1965, p. 272).

and so on. Similarly, cause and reason may not now be regarded as *two* equivalent explanatory types of special significance. Rather, reason is seen to represent a particular type of explanation, whereas cause is seen to represent explanation in general or nonreason-type explanation in general. Thus, we seem to have an infinity of explanatory types of which teleological explanation is but one. In the following section this type of explanation is considered in further detail.

Teleological and Nonteleological Modes of Naive Explanation

Two major questions with which Buss (1978) deals at length are (a) whether nonteleological (in his terms, *causal*) explanations of actions and/or teleological explanations of occurrences may be possible and (b) *who* (actors, observers, or both?) may be capable of nonteleological versus teleological accounts of actions or occurrences. In his answers Buss implies that nonteleological accounts of actions are in principle possible, although they may be given by observers only, not by actors: "*action* . . . is explained by the actor with reasons. The observer may use causes and/or reasons in explaining action" (p. 1311). By contrast, occurrences (i.e., events devoid of intentionality) are assumed to be explicable only nonteleologically: "*occurrence* . . . is explained by both actors and observers with causes" (p. 1311). In the forthcoming section I closely examine Issues a and b above and comment on Buss's proposed answers.

Are Nonteleological Accounts of Actions and/or Teleological Accounts of Occurrences Possible?

The answers to these questions depend on how one chooses to define teleological and nonteleological explanations. If by nonteleological explanation is meant explanation that denies the behavior's purposive character, a nonteleological explanation of actions is impossible by definition. I suspect, however, that for most people a teleological explanation is merely one that identifies the actor's reason for a behavior. For example, one might (teleologically) account for Mark's application to Harvard Law School by mentioning his hope of joining the family law firm, thus explicitly identifying the behavior's underlying reason. Similarly, one might (teleologically) explain Sara's departure for a skiing trip by labeling it an end in itself, which again implicates the action's instigating reason (Sara's desire to ski; see, e.g., Kruglanski, 1975, Derivation 9, p. 302).

Granting the above definition of teleological explanation, a nonteleological explanation would be one that is mute with respect to the actor's specific reason for a behavior. Further, because actions alone may have underlying reasons (purposes, etc.), if a teleological explanation is given, it follows logically that the event explained was an action. The obverse does not follow, however: Given that an action was explained, the explanation must not necessarily have been teleological. For example, one might nonteleologically account for John's application to Harvard in terms of his upbringing, which does not clarify John's specific reason for the action. Similarly, one might explain Paul's decision to undertake some job in terms of the situation (most people in it would have done the same) or in terms of Paul's personality (only someone like him would have done so), again without illuminating Paul's specific reason for the decision. Assuming the interpretation of cause as nonreason (the exclusive interpretation given earlier), Buss seems correct in implying that nonteleological accounts of actions are in principle possible.[2]

Finally, if the essence of teleological explanation consists of identifying the actor's reason, such explanation may not logically be possible with reference to nonintentional behaviors. One cannot identify something that is not there, that is, a purpose in a nonintentional behavior. Assuming the exclusive interpretation of the cause concept, Buss's asser-

[2] This is contrary to Postulate 1 of my endogenous–exogenous article (Kruglanski, 1975, p. 389), which implies that nonteleological explanation of actions may not be possible. Assuming the present definition of teleological and nonteleological explanation, the above implication of Postulate 1 must now retracted.

tion that occurrences must be explained causally by all actors as well as observers simply means that they may not be explained teleologically. This follows tautologically from the definition of occurrences (as nonintentional behaviors devoid of reasons) and must be considered quite indisputable. Let us consider now an issue on which Buss's claims may not seem as cogent: the hypothesis of actor–observer differences in the rendition of teleological and nonteleological explanations.

Are Observers Alone Capable of Nonteleological Explanations for Actions?

Buss provides two separate arguments for the contention that observers alone, and not actors, can explain action nonteleologically. According to one argument,

> The actor's "because" statements consist of giving his or her reasons for an action, that is, matters that weighed in on his or her deliberation. By definition, in giving one's reasons for an action, only matters that are *consciously* available to the actor can occur in such explanations. In contrast, the observer who is asked to explain "why" in regard to an actor's action can include causal attributions that operate *out* of consciousness of the actor. Thus, while an observer can make causal attributions in explaining the action of an actor . . . , the actor's explanation could not include such kinds of attributions. . . . (Buss, 1978, pp. 1315–1316)

According to the second argument: "In asking an actor to explain his or her action, the 'why' is a request to justify, or to make rational or intelligible, his or her action vis-à-vis society's norms for 'proper' conduct . . ." (p. 1315). I now examine the two foregoing arguments in turn.

The differential-consciousness hypothesis. Turning to the former argument, it may be readily conceded that only matters available in one's consciousness can figure in one's explanations and that the contents of actors' consciousness may systematically differ from those of observers' consciousness. Such differences have usually been interpreted as an informational advantage of actor over observer, as the former person more than the latter may be cognizant of his or her own bodily reactions or of the details of his or her own personal history. But it is difficult to see how an excess of information may prevent the actor from formulating explanations of which an observer may be capable.

More generally, granting that a nonteleological explanation is merely one that stays incommunicative with respect to the actor's reason for a behavior, it still remains to specify *what* in the actor's consciousness might prevent this person from arriving at explanations in this class. In fact nonteleological explanations of a person's own actions seem quite commonplace; criminal activity is often explained with reference to the adverse social conditions during the criminal's childhood, and a hostile act may be accounted for in terms of the perpetrator's tension or irritability.

The justification hypothesis. Buss's second argument for the actor's presumptive inability to formulate nonteleological accounts of his or her own behavior assumes that (a) the actor's accounts of personal actions are necessarily justificatory (Buss, 1978, p. 1315) and (b) all justificatory accounts of actions are necessarily teleological. On close inspection, both of the foregoing premises appear questionable. The first appears unwarranted if *justificatory* is taken in the sense of normatively excusable (this seems implied in Buss's reference on p. 1315 to society's norms and rules for "proper" social behavior). Surely an actor may occasionally admit to socially unwholesome motives (greed, cowardice, vengeance) or to reasons that are normatively neutral, as when one explains a trip to the grocery store by reference to the empty cupboard at home.

If by justificatory is meant, more broadly, intelligible or plausible accounts (excusable or not; cf. Buss, p. 1315) then Premise b would still seem doubtful. Many intelligible accounts of one's own behavior may be nonteleological, as in the earlier example of the criminal who may account for deviant actions in terms of the deleterious social circumstances in his or her neighborhood. Finally, if by *justificatory* is meant *rational* (Buss, p. 1315) and by *rational* is meant *teleological*, then accounting for the actor's presumptive need to give teleological explanations by invoking the need to give justificatory explanations would be circular, hence devoid of

clarifying value. The preceding discussion shows that Buss's hypotheses of actor–observer differences, relying on teleological (vs. nonteleological) explanations, are largely unsupported.

The Cause–Reason Distinction in Attribution Research

According to Buss, the failure of attribution theorists to draw the distinction between causes and reasons has resulted in much conceptual confusion. This is illustrated in reference to two research topics: (a) Jones and Nisbett's (1971) hypothesis of actor–observer differences in attribution and (b) Kruglanski's (1975) partition between endogenous and exogenous attributions. Let us examine Buss's specific comments on these issues.

Jones and Nisbett's (1971) Actor–Observer Hypothesis

In a classic attributional essay, Jones and Nisbett (1971) speculated, "actors attribute cause to situations while observers attribute cause to dispositions . . ." (p. 82). Buss (1978, p. 1316) regarded the above formulation as objectionable, for it contradicts his aforementioned assumption that actors (unlike observers) are fundamentally incapable of causal (i.e., nonteleological) accounts of their own behaviors. Furthermore, Buss viewed as categorically mistaken statements (occasionally made by researchers in the actor–observer paradigm) conjoining the *actor* term with nonintentional behaviors like nervousness and physiological reactions to music or emotional responses.

But from the present perspective the problems identified by Buss are not as serious as has been alleged. The statement "actor attributes cause for own behavior" may be taken in the inclusive sense of cause to mean simply that the actor explains his or her own behavior (indeed, I strongly suspect this to have been Jones and Nisbett's intent in the first place). But even if cause is interpreted exclusively as a nonteleological explanation, it follows from the preceding section that actors should be capable of attributing cause (for their own behavior) if observers are capable of such attributions.

As for the linkage of the *actor* term with nonintentional behaviors (occurrences), the contradiction identified by Buss exists only if actor is narrowly interpreted as producer of intentional behaviors. If actor is taken in the broader (if somewhat Pickwickian) sense of target person whose responses (voluntary or not) are being explained (an interpretation that I again believe better captures Jones and Nisbett's intent), however, the apparent contradiction exists no longer. Generally, the hypothesis of Jones and Nisbett (1971) implicates the differential preference of behaving individuals (actors, target persons) versus the observers of such persons, for situational versus dispositional explanations of the behaviors at issue. In present terms, both situational and dispositional explanations are nonteleological: They do not name specific reasons, if such reasons are indeed involved in the behaviors observed. As we have seen, actions as well as occurrences may be explained nonteleologically, and actors (target persons) as well as observers seem capable of nonteleological explanations. Hence, contrary to Buss's reasoning, Jones and Nisbett's hypothesis seems conceptually coherent, and its case would have to rest ultimately with empirical research.

Finally, to the extent that neither the person nor the situation categories are classifications of reasons, the cause–reason distinction is not particularly relevant to the paradigm of Jones and Nisbett. The distinction's relevance hinges entirely upon relevance of the reason concept to a given domain of phenomena, the residual concept of cause signifying merely a nonreason, that is, containing no unique meaning independent of the reason notion.

The Endogenous–Exogenous Partition

Buss's second example of confusion due to failure to differentiate between cause and reason recalls the theory of endogenous (vs. exogenous) attributions (Kruglanski, 1975) concerned with the case in which action is assumed to be an end in itself (endogenous

attribution) rather than a means to a further end (exogenous attribution). As Buss (1978, p. 1318) correctly points out, Postulate 1 of the theory implies a distinction between causal and teleological explanation in stating that "the lay explanation of actions is teleological rather than causal" (Kruglanski, 1975, p. 389). But subsequent portions of the same article contradict the distinction in speaking about "causally attributing actions . . . " and in implying the interchangeability of causes and reasons (p. 389).

The foregoing criticisms by Buss seem quite valuable: (a) They demonstrate a clear inconsistency in my usages of the causality notion throughout the 1975 article, and (b) they highlight an authentic shift of views between my 1975 work and my current reasoning. While Postulate 1 of the former article denies the possibility of explaining actions nonteleologically, such a possibility has been explicitly affirmed throughout the present essay.

Finally, note that the endogenous and exogenous categories refer to teleological explanations, so the notion of reason would seem quite pertinent: Implications drawn from an endogenous attribution (Kruglanski, 1975, pp. 391–392) follow without exception from its being a classification of reasons. In agreement with Buss (p. 1320), we may therefore conclude that the reason concept is of considerable significance to the endogenous–exogenous paradigm.

In sum, the concept of reason (and the derivative explanation type called *teleological*) could be of relevance to some domains of attributional research (like that of endogenous vs. exogenous attributions) while being irrelevant to alternative attributional domains (like that of actor–observer differences). What then can be safely concluded about the concept's significance for attribution theory at large? This issue is specifically addressed in the following section.

The Reason Notion and the Content Problem in Lay Epistemology

The main thrust of Buss's analysis has been for the inclusion of teleological (reason-type) explanations within the purview of attribution theory. I readily concur with the suggestion: The recognized province of attribution theory is lay explanation; a teleological account is one type of lay explanation, so it should properly fall within that province.

But it is one thing to concede the applicability of attribution theory to reason-type explanations and quite another to pronounce the reason–cause distinction as of key importance (see Buss, 1978, p. 1311) within the theory. Such centrality would certainly be implied in a scheme that regards the reason and cause categories as the unique classificatory scheme for explanations. But according to the present view there is nothing unique about classifying explanations into causes and reasons. As noted earlier, the concept of cause as distinct from reason seems best interpretable as a nonreason, that is, as representing an open class encompassing a potential infinity of explanation types. In other words, reason-type or teleological explanation is merely one of an infinite number of possible explanations. Furthermore, viewed now as it separates reason from nonreason, the reason–cause partition may be compared to the possible distinctions between (any of the infinite) explanatory categories and their complementary classes, for example, mechanical versus nonmechanical explanations, biological versus nonbiological explanations, and so forth. In sum, attribution theory deals with the *general* case of explanation, so any distinction (like that between reason and cause) based on a *specific* type of explanation (out of the infinity that are possible) must be of a vanishing significance with the theory.

But matters will now become even more extreme. We have already seen that the class of teleological statements (reason-type explanations) is a subset of the class of all explanatory statements and that the latter class defines the recognized purview of attribution theory. But obviously the class of explanatory statements (those constructed around the because preposition) is a subset of the class of all statements, and I shall now argue that it is the latter class that defines the domain of a general epistemological theory, of which attribution theory is merely a special case.

Within this general epistemic theory *any* classification of statements (as explanatory or as teleological) turns out to be of vanishing importance. Therefore, the attribution framework, constrained as it may be to explanatory statements, deals with an extremely small segment of the domain to which general epistemological laws are assumed to apply.

The epistemic theory presently referred to (and elaborated in Kruglanski et al., 1978 and in Kruglanski & Bar-Tal, Note 1) rests on the partition between the contents of knowledge (epistemic contents) and the process of knowledge acquisition (epistemic process). Epistemic contents are all propositions whose validity a person might, on occasion, wish to ascertain—in principle, all propositions. The epistemic process is the sequence of cognitive operations performed by an individual on the way to a given bit of knowledge. The terms *process* and *content* figured prominently in the recent debate about transhistorical laws in social psychology (see, e.g., Gergen, 1973, 1976; Hendrick, 1976; Manis, 1975, 1976; Schlenker, 1974, 1976; Thorngate, 1975), although their meaning in that context differed from the present one. To clarify matters, the distinction between the two usages is now considered at some length. As presently employed, process refers to systematic change and content to the object of such change. In this sense, the distinction between epistemic process and content parallels the distinction between the metabolic process and the biological system and between the evolutionary process and the evolving species, to name only two examples.

The foregoing interpretation must be sharply distinguished from that in which process denotes the abstract or the general level and content the concrete or the specific level. It is the latter meaning of the process–content partition that has characterized the social-psychology-as-history debate just mentioned. For example, in denying the feasibility of process invariance in social psychology, Thorngate (1975, p. 487) referred to "*local* organization" (meaning contents) and "*general* disorganization" (meaning process, italics mine). Gergen (1976, p. 376) similarly asserted that in speaking about "processes underlying social behavior we are dealing with a hypothetical structure suitable for encapsulating a series of selected observations . . . ." (i.e., a series of social contents). In the same vein, Manis (1976) proposed that "the development of a scientific theory . . . involves the construction of some hypothetical mechanism or process that lends coherence to an otherwise chaotic set of particulars" (p. 431). Thus, reinforcement is cited as a theoretical term representing process, and a specific classroom event, as a particular instance of reinforcement, that is, content.

It is stressed that the two foregoing interpretations of process versus content are quite orthogonal. Both change and the object of change may be conceptualized on a variety of abstraction levels, and neither may be exclusively identified with the abstract or the specific level. For example, one might particularistically describe a sequence of physiological changes transforming a given child into an adult at a specific time and place, or one might refer to the very same event sequence more abstractly as an instance of the maturation process. Similarly, the child (the object of change) might be particularistically identified as Johnny Smith or might more abstractly be referred to as child, mammal, or physical body.

The last example serves to underscore the relativity of abstraction levels; mammal is an abstract class of which human child is a particular instance, but mammal is itself a particular instance of the organism class, which in turn is a particular instance of the physical object category, and so forth. Interpreting process as the abstract and content as the specific, it is indeed correct to assert that "one man's process is another's content" (cf. Hendrick, 1976, p. 395). But the relativity hardly extends to the alternative interpretation of process and content mentioned earlier. To confuse change and the object of change would represent a gross mistaking of category (Ryle, 1949), of which few persons would be guilty.

While in the present usage the generic categories of process and content are not presumed to differ in level of abstraction, a particular content could still be the object of numerous particular processes, and a par-

ticular process could still apply invariably across multiple particular contents. Thus the (same) human body may be the object of multiple different processes: growth, maturation, aging, disease. Conversely, the process of evolution may invariably apply to all biological species, and the process of metabolism to all living organisms. In precisely this last sense it is presently assumed that the same epistemic process discussed below underlies the acquisition of all epistemic contents:[3] The sequence of cognitive operations that a knower may perform is assumed to be invariant regardless of the kind of knowledge that this knower may seek.

In light of the foregoing assumption it is now possible to appreciate the sense in which any classification of statements may be of a vanishing significance for the general epistemic theory: (a) Statements may be classed in a vast number of ways, based, for example, on their inclusion of any of the vast number of concepts that man may be competent to construct. Thus, the designation of statements as explanatory derives from their inclusion of the concept of the conditional (if-then) relation (see Footnote 1), but it is possible to devise numerous alternative classifications based on alternative included relations (e.g., the various geometric, social, or biological relations). (b) In the present framework any classification of statements is a classification of epistemic contents to which the same epistemic process is assumed to apply; for example, the process of explanation (the acquisition of so-called causal knowledge) would be no different from that involved in the acquisition of any knowledge, including nonexplanatory (noncausal) knowledge. It therefore follows that any classification of statements (any categorization of epistemic contents) may be of extremely limited import for the general theory of knowledge and that the theory might best focus instead on the epistemic process.

A detailed discussion of epistemic process is well outside the scope of the present essay (the interested reader is referred to Kruglanski, 1977; Kruglanski et al., 1978; or Kruglanski & Bar-Tal, Note 1), but passing consideration of its major attributes is necessary. Briefly, it is hypothesized that (a) the epistemic process is purposive, that is, it is initiated by the individual's purpose to acquire a given bit of knowledge. Furthermore, the process involves (b) the formulation of an epistemic problem the solution of which may advance the knower's purpose, (c) the generation of conjectures regarding the identity of such a solution, and (d) the deductive assessment of such conjectures by checking their implications for (logical) consistency with available evidence.

The epistemic problem just referred to is conceptualized as a set of mutually exclusive propositions on some topic, among which a knower might wish to choose. Only some epistemic problems may be explanatory, that is, revolve about because-type propositions; other epistemic problems may not, in this sense, be explanatory. For an example of an explanatory problem, consider someone choosing among the propositions "John laughed at the comedian, (only) because of himself," "John laughed at the comedian (only) because of the comedian," and "John laughed at the comedian (only) because of the circumstances."[4] For an example of a nonexplanatory problem, consider someone choosing among the propositions "The way to the market lies to the left," ". . . to the right," or "directly ahead."

The same epistemic process is assumed to be involved in both examples and in all other cases of epistemic behavior. For instance, an individual would not usually wonder about John's laughter or about the way to the market unless he/she had a purpose for wanting to know those things. Furthermore, in tackling any epistemic problem the lay inquirer would be likely to form conjectures about the correct resolution. For example, one might conjecture that John laughed at the comedian because of

---

[3] As with any scientific proposition, the assumption of process invariance in this case is not intended as an a priori truth but as a hypothesis open, in principle, to empirical test. In this connection it is of interest to note that at least some suggestions regarding the presumptive diversity of epistemic processes (e.g., Kelley's, 1971, 1972, proposals for separate attributional principles and schemata) are interpretable as instances of the same epistemic process applied to different contents of knowledge (cf. Kruglanski & Bar-Tal, Note 1).

[4] Roughly modeled after problems employed in McArthur's (1972) research.

himself or that the way to the market lies to the left. Such conjectures would then be tested via a deduction of some of their implications and the assessment of these against relevant evidence. Thus, the hypothesis that John laughed because of himself implies that he would also laugh on other similar occasions, that other people would not laugh similarly, and so forth. Data consistent with such implications would augment the knower's confidence regarding the correctness of the conjecture involved (as has been demonstrated empirically by McArthur, 1972). Similarly, with a nonexplanatory problem, the hypothesis that the way lies to the left implies among other things that if one pursued the path to the left one would eventually wind up at the market. Evidence consistent with such an implication would again bolster the knower's confidence regarding the validity of the hypothesis at stake.

The above discussion suggests that the same epistemic process may be involved in the acquisition of diverse epistemic contents. From a standpoint of scientific generalization it would thus seem that we should have a unitary theory of process applicable alike to divergent contents of knowledge. Still, an individual's epistemic behavior in a specific instance should vary considerably as a function of the contents investigated. Someone wishing to account for John's laughter would thus care very little about the consequence of turning left at the crossroads, similarly, someone interested in reaching the market would be indifferent, for example, to John's behavior toward various comedians. If so, the question arises whether the theory of epistemic process may not be profitably supplemented by various theories of content, that is, by the specification of various content categories that the lay person may occasionally employ in the course of epistemic behavior. Indeed, extant attributional formulations have frequently included various such categories, for example, those of internal versus external causality (cf. Kelley, 1971), of endogenous versus exogenous causality (cf. Kruglanski, 1975), of ability, luck, effort, and task difficulty (cf. Weiner, 1974). In this sense Buss's proposal to include the reason category within the attribution framework jibes well with an already popular trend in attributional theorizing.

Still, an immense difficulty with any program of constructing content-bound epistemic models (those constructed around specific concepts or statements in the layman's repertory) is their potentially infinite variety. For exactly the same reason, the program of the ordinary-language philosophers, to explicate the terms in everyday discourse, can hardly be expected to get off the ground. The everyday discourse may contain an infinity of terms, so the task of their explication may only begin but never end.

Furthermore, people across cultures and historical periods may have vastly different conceptual repertories and so must deal in epistemic contents that may vastly differ. Hence, an epistemological theory constrained to specific elements of content (e.g., to explanatory propositions or to special kind of explanatory propositions) seems condemned to the throes of cultural and historic relativism (see, e.g., Gergen, 1973, 1976). Finally, to the extent that a normal person may pose divergent epistemic problems across varying occasions, an epistemic (or attributional) framework restricted to a narrow set of contents is perforce situationally specific and particularistic. Thus, we may not have content elements in an epistemological theory for the very same reason that we must have a unitary theory of epistemic process: the fundamental scientific commitment to generalization. The contextually shifting contents of relevant knowledge, while undoubtedly essential to the full understanding and prediction of human conduct, must be divined specifically for each new situation rather than derived from an invariant set of principles.

On the Relationship Between Causes and Reasons

Allan R. Buss
University of Calgary, Calgary, Canada

Criticisms (Harvey & Tucker, Kruglanski) of my recent conceptual critique of attribution theory are criticized. Further analysis of the distinction between cause and reason is undertaken, where their relationship is set forth in terms of the growth of knowledge (at both the individual and the collective level). The model involves converting causes into reasons and makes use of the psychoanalytic therapy session as an analogue for purposes of explicating the process.

Reply to Harvey and Tucker

Although Harvey and Tucker (1979) would seem to agree that the cause–reason distinction is valid and important for attribution theory, they are somewhat concerned about what they regard as certain logical and empirical problems inherent in my analysis (Buss, 1978).

In regard to logical matters, Harvey and Tucker believe that the distinction between "action" and "occurrence" is not an easy one to make. Thus they point out that physiological responses are often susceptible to conscious and deliberate control, thereby rendering them actions rather than occurrences. I quite agree, and am glad to see that my earlier example of just such a situation (Buss, 1978, p. 1318, footnote 6) did not go unnoticed.

A second example in their attempt to demonstrate some logical problems in this area concerns intelligent behavior. Their point here is that because intelligence rests in part upon uncontrollable innate factors, intelligent behavior is somehow less an action. I would like to know what behavior, including any conceivable action, is not dependent upon or affected by innate factors (as well as environmental factors)? The point is that the person engaged in intelligent behavior *freely* forms an intention to act. The limits and/or constraints surrounding the action do not make it less an action. Even if the test giver holds a gun to the test taker's head and orders him/her to complete the latest IQ test, such behavior would constitute action, since the test taker still does have the option to refuse. Thus, the distinction between action and occurrence is *conceptually* and *logically* relatively straightforward, given sufficient analysis.

When we move into the realm of empirical matters, defined here as experimental social psychology, then I quite agree with Harvey and Tucker that there are problems. Why shouldn't there be, considering that the distinctions that I have stressed are *conceptual* rather than empirical? How could one operationally define a reason or a cause, an action or an occurrence? I cannot think of any simple way. I do think that an experimenter sensitive to the conceptual issues I have raised can arrange the task demands such that there is an avoidance of category errors. Reason and logic will guide the experimenter here. I cannot offer a pat formula. My whole point was to alert attribution theorists to the conceptual confusion in their area. If they themselves cannot remedy such confusion in their concrete researches, as Harvey and Tucker would seem to imply, then they should abandon this type of research. My challenge cannot be thrown back to me, since it rests with those who consider themselves attribution theorists and who believe that their ex-

perimental program has some potential to enlighten us about lay explanation.

Reply to Kruglanski

Kruglanski (1979) has argued that causal explanation (efficient cause) is a generic form of explanation and that reason explanation (final cause) as well as Aristotle's other two types (formal cause and material cause) are "merely" special instances of efficient causality. In other words, Kruglanski is a monist, a scientific monist in the grand tradition of Hempel (1966), who attempted to reduce Dray's (1957) use of reasons in historical explanation to a special case of efficient causality. The point, however, is that reasons and causes are truly distinct logically. Perhaps the best explication of this distinction available to psychologists is Harré and Secord's (1973), especially chapters 1, 2, and 8:

> In accounts of human action reasons appear in a justificatory context, and logically imply the propriety of a happening, as opposed to its existence, which would follow from the description of its cause. (p. 148)

Thus the connection of reasons to an event is *logical*, whereas that between causes and an event is *physical*, that is, space/time. This analysis is, I think, the best thus far, and it avoids the necessity to totalize *either* causal explanation à la Hemple (and most recently Kruglanski) *or* reason explanation à la Winch.

In the same article, Kruglanski states that there are an infinite number of kinds of explanation. He cites mathematical, mechanical, geographic, demographic, social, and other types. Now, any of these types of explanations *can* be classified or reduced to one or more of Aristotle's four basic types. Kruglanski has confused form and content.

Kruglanski does make the valid point that actors are not necessarily required to give a reason account of their action and in fact may offer a causal explanation. I think my initial position, claiming that actors can only give a reason account of their action, was too extreme. It would seem that both causes and reasons could figure in an actor's self-explanation. However, I think that Harré and Secord (1973) make an important point in this connection when they state, "For 'propaganda' purposes some justificatory reasons are passed off as causes, as e.g., in the substitution in common speech of 'need' for 'want'" (p. 149). The example they give concerns the alcoholic who states that he/she "needed" a drink (implying uncontrollable causal factors) rather than that he/she "wanted" a drink (implying reasons that fail to justify the action). To the extent that taking a drink is difficult to justify, the actor will try to offer a causal explanation the validity of which is suspect.

On the Relationship Between Causes and Reasons

Let me now attempt a more explicit analysis of the distinction between cause and reason by elaborating upon their relationship. In maintaining a logical distinction between causes and reasons, I would not claim that there is no relationship between them—in fact, quite the contrary. The first point to note in this regard is that a cause *may* be cited as a reason, that is, it may figure in one's justificatory explanation. However, *not* all reasons are causes, since not every reason would have the space/time or antecedent–consequent connection to an event. This view is an extension of my previous position rather than being inconsistent with it.

The second matter to consider in the relationship between causes and reasons is more complex and involves the process of actually converting causes into reasons. A model that illustrates just such a relationship between causes and reasons has been developed and described by Apel (discussed in Radnitzky, 1970), Habermas (1971), and Ricoeur (1970), as well as Taylor (1973), where the context is arriving at increased knowledge of self. Essentially, the model involves the dialogue between patient (actor) and therapist (observer) in the psychoanalytic encounter. As long as the actions of the patient can be understood by his/her offering reasons (thereby arriving at valid intersubjective meanings, i.e., the *point* of the action is intelligible to both patient and therapist), then there is no need for the therapist (observer) to introduce

hypostatized causal forces. When there is a breakdown in a reason account of action, however, it is then necessary to resort to causal analysis, where the therapist (observer) attempts to formulate a causal explanation involving unconscious or hidden motives. To the extent that these causal factors are brought into the patient's (actor's) consciousness (through the technique of appropriately timed interpretations—thereby facilitating "insight"), then, according to the above-mentioned individuals, they *cease functioning as causes* and become matters for deliberation, that is, reasons. Thus the road toward greater self- (reason) understanding and emancipation from hypostatized causal forces lies in *converting causes into reasons*. In this way, causal analysis mediates, or is in the service of, greater (reason) understanding.

The psychoanalytic encounter and the growth of self-knowledge operate at the individual level, and Habermas especially has generalized this basic paradigm to the collective enterprise of the growth of knowledge in the social or human sciences. Revealing the underlying social forces or causes of nonliberation requires criticism grounded in the emancipatory interest. At the social level, bringing into consciousness previously unknown hypostatized forces—causal forces that hinder greater self- (reason) understanding at a social level—will, of necessity, take the form of a critique of ideologies. When previously hidden social forces are brought into consciousness, they become matters of deliberation, that is, are converted into reasons, and are thereby made not to function causally.

We can be somewhat critical of the boldness of the claims of Apel, Habermas, Ricoeur, and Taylor regarding the conversion of causes into reasons and the supposed neutralization of the causal efficacy of the cause in question as a result. If only matters were that simple and straightforward! Unfortunately, as critics of the role of insight in psychotherapy have pointed out (e.g., Hobbs, 1962), there is often no change in maladaptive behavior even after sufficient insight has been demonstrated by the patient, that is, after previously unconscious causes are brought into consciousness. According to what we might aptly dub the "conversion model," the causes should cease to function once they enter consciousness and become matters for deliberation (reasons). Since this is often not the case in the psychoanalytic encounter and most certainly does not apply to becoming conscious of previously hidden social forces, it is necessary to add a very important qualification to the conversion model.

The necessary qualification of the conversion model is that the bringing of previously hidden causes into consciousness—and the institution or creation of new reasons by this means—does not ipso facto neutralize or destroy the original cause. Rather, when a cause is converted into a reason, the cause may still operate, but now the awareness of that cause may *potentially* lead to eventual elimination of the cause qua cause. Thus, the conversion of causes into reasons may (but not necessarily) provide for deflating previously unconscious causes of their causal power.

The modified conversion model proposed here permits going beyond the implications of attribution theory for psychotherapy that have thus far been considered. Storms (1973), Storms and Nisbett (1970), and Valins and Nisbett (1972) have all discussed both the desirability of and the means for having the patient (actor) adopt more of an observer perspective with respect to his/her action. In this way, the patient (actor) would tend to give more dispositional or self-attributions in explaining his/her inappropriate or maladaptive action and would thereby assume greater responsibility for it (and thus, presumably, greater responsibility for changing it). The modified conversion model permits us to be a little more sophisticated in understanding how, in fact, a greater frequency of internal attributions made by the patient (actor) can work toward the goal of greater self-understanding and emancipation. That is to say, as a person becomes more self-conscious of previously unconscious internal causes vis-à-vis maladaptive behavior, such causes may (but not necessarily) be made causally impotent through conversion into reasons.

However, it should be noted that a higher frequency of internal causal attributions on the part of the patient (actor) is not in and of itself desirable if the attributions are not valid. Storms (1973; see also Galper, 1976) did recognize that increasing the number of self-attributions may actually lead to an exacerbation of the pathological behavior if the causes of such behavior are external. The modified conversion model also goes beyond abstract individual liberation by incorporating unconscious social causes of nonliberation within its framework. Thus one must guard against the reification of abstract internal causes (dispositions), as well as abstract external causes (situations), and adopt more of a dialectical view of subjective (internal) and objective (external) forces. Viewed in this way, the successful conversion of causes into reasons, and thus the achievement of greater human emancipation, is two dimensional rather than one dimensional.

Conclusion

Causes and reasons are both (a) logically distinct and (b) intimately connected to each other. In order to understand truly the nature of lay explanation, it is necessary to take cognizance of both of these conclusions. If attribution theorists will not or cannot do this (because of the inherent limitations of their experimental methodology and philosophy of science), then they should give up any pretense that they are better able to explain lay explanation than are the lay explainers.

Competence and the Overjustification Effect: A Developmental Study

Ann K. Boggiano and Diane N. Ruble
Princeton University

This study examined the conditions under which information regarding competence would mitigate the negative side effects of rewards on the intrinsic interest of preschool and middle elementary school children. Children engaging in a task of high initial interest anticipated a reward made contingent either upon meeting a standard based on absolute performance level or upon task engagement alone, or they were not rewarded. In addition, they were provided with direct information concerning competence presented in terms of social comparison. The pattern of results indicated that the preschool children were primarily affected by information about meeting the absolute standard but not the social comparison information. That is, the overjustification effect did *not* occur when attaining a reward was made contingent on meeting an absolute standard of performance. In contrast, social comparison information superseded the effect of the contingency of the reward on subsequent interest in the target task for the older children. These findings suggest the importance of research from a developmental perspective for attempts to delineate the conditions under which rewards may avert the undermining of intrinsic interest.

A number of researchers have demonstrated that offering a reward to a person for engaging in an otherwise enjoyable activity will undermine that person's subsequent interest in that activity when the reward is discontinued—a phenomenon typically explained by means of an attributional analysis (Bem, 1972; Nisbett & Valins, 1971) and termed the *overjustification effect* (Lepper, Greene, & Nisbett, 1973). That is, if the justification for having undertaken an interesting task is perceived to be an overly sufficient reason for task engagement (e.g., an extrinsic incentive), the person would then infer that behavior was motivated by the reward itself rather than by enjoyment, thereby decreasing interest in the target task when the reward is no longer available. A substantial number of studies have shown the reliability of this effect across both types of reward and population (cf. Condry, 1977, Deci, 1975; Lepper & Greene, 1978; Ross, 1976).

The overjustification effect, however, is not assumed to be an inevitable result of reward attainment. Based on theories postulating that intrinsic interest stems from perceptions of competence and self-determination (Deci, 1975; White, 1959), several investigators have hypothesized that rewards conveying information regarding competence should sustain rather than undermine subsequent intrinsic interest (Arkes, 1978; Lepper & Greene, 1978). Specifically, it has been argued that level of intrinsic interest should vary directly with information regarding competence or incompetence that is conveyed by means of reward systems.

A few lines of research have provided some support for the competency hypothesis. Recent research has demonstrated that a reward made contingent on meeting a performance

The authors are grateful to Mark Lepper, Michael Ross, Thane Pittman, and Nina Feldman for many helpful suggestions on an earlier draft of this paper, and to Jeanne Courtright, Barbara Hoyler, and Paget Gross for their invaluable assistance in collecting the data.

standard produces more interest than a reward made contingent on task engagement alone, as shown in both behavioral (Karniol & Ross, 1977) and attitudinal measures (Enzle & Ross, 1978). These results were interpreted as suggesting that rewards made contingent on successful performance provide cue value regarding competency at the task, thereby maintaining intrinsic interest. Similarly, research using a social reward paradigm has shown that task-related praise sustains or even enhances intrinsic interest (Anderson, Manoogian, & Reznick, 1976; Deci, 1975; Pittman, Davey, Alafat, Wetherill, & Wirsul, in press; Swann & Pittman, 1977). This body of research, then, has provided indirect support for the competency hypothesis by demonstrating that intrinsic interest is not undermined when reward is conveyed by means of verbal feedback or is made contingent on successful performance.

The primary purpose of the present study was to test the competency hypothesis by manipulating the availability of *direct* information about competence. That is, although intrinsic interest should be maintained when reward attainment is made contingent on an absolute performance standard, the competency hypothesis would predict that if more direct information about competence or incompetence is additionally provided (in this case, performance level relative to others), subsequent level of interest should vary directly with the type of information regarding competence that is presented.

The competency hypothesis was also assessed by means of a developmental analysis of the effect of different kinds of competency information on intrinsic interest. According to Veroff's (1969) developmental theory of achievement motivation, it is not until 7–8 years of age that children derive feelings of competence from *comparative* standards of excellence; however, even very young children (e.g., preschoolers) are assumed to make evaluative judgments regarding their level of competence based on *absolute* performance standards. Evidence supporting these propositions is provided in several recent studies (e.g., Ruble, Parsons, & Ross, 1976; Ruble, Boggiano, Feldman, & Loebl, in press). These developmental findings suggest an alternative explanation for the results of one recent study where rewards made contingent on a comparative standard were *not* found to sustain subsequent interest in nursery school children (Greene & Lepper, 1974). Specifically, the findings described above would suggest that this failure to support the competency hypothesis may have been because young children do not use comparative information in making self-evaluations of competence. Thus, if the findings of the present study supported the predictions that competency information conveyed in relative terms mitigates the undermining effect of reward for older but not for younger children, additional support for the competency hypothesis would then be obtained.

In the present study, children at two age levels engaged in a task that pilot testing revealed to be highly interesting for both groups. Upon completion of the target task, children were provided with competence information in terms of relative and/or absolute level of performance, which was predicted to avert the undermining effect of reward on intrinsic interest. However, the two types of information concerning competence (absolute vs. relative) were expected to affect the children differentially at the two age levels in the manner described above.

To test these hypotheses, children in the experimental conditions anticipated a reward made contingent either upon task engagement alone or upon meeting a performance standard (i.e. competence information based on absolute performance level). In addition, the children were either provided with information regarding their performance relative to peers (i.e. competence/incompetence information conveyed directly in terms of social comparison) or were not provided with this information. Finally, a no-information-regarding-competence/no-reward group was included as a baseline control.

Method

Subjects

Subjects were 147 children of predominantly middle-class backgrounds drawn from two private nursery schools and two public elementary schools in

central New Jersey. Three children were excluded from the analyses for reasons explained below. The nursery school children ranged in age from 3–5 to 5–8, with a mean age of 4–6, whereas the mean age of the elementary school children from grades 3 through 5 was 9–11. An attempt was made to distribute subjects equally by sex across each cell. Since preliminary analyses revealed no interaction of sex or experimenter with experimental conditions on any measure, the data were collapsed across these variables for purposes of analyses.

Procedure

The children were escorted individually into a mobile trailer parked near their school. After one of four female experimenters (three of whom were blind to the hypothesis) demonstrated to the children the different activities that she used with children from different schools at various times, she then told the children that they would have the opportunity to play the "find the hidden pictures" game.

The hidden picture game consisted of a stack of eight embedded figure tasks with five to eight embedded figures on each of the eight papers. The children were told that the object of the game was to find and circle the *one* particular thing on each of the eight papers which they would be instructed to circle after they turned on a tape recorder. They were also told that they should work as quickly as possible since they would have to proceed to the next picture when the person on the recorder instructed them to turn the page. Subjects were told, however, that they could find and circle other hidden pictures on each of the pages if they wanted to and had sufficient time. The children were given two practice trials on an additional embedded-figure task to ensure comprehension of the task and were also given the opportunity to practice using the recorder to facilitate recognition of the different switches (the "on" button was painted green and the "off" button was painted red). The colors and game context of the task (i.e. finding and circling one hidden picture on each page) were all designed to enhance the interest value of the task. Pilot testing did, in fact, reveal that this task was highly interesting for the two age groups. The interest value is also indicated by the high percentage of time the subjects in the baseline control condition played with the task.

After the practice session, subjects were shown the scoreboard that displayed numbers ranging from 0 to 8. Children in the performance-contingent reward conditions were told that they could earn two Hershey's Kisses *only* if they obtained a score of at least 3 out of a possible 8. Stars were painted above the numbers 3 through 8 to ensure comprehension of the absolute performance criterion, which they were told meant that they did "okay" at the game. Children in the task-contingent reward conditions were given the same information as children in the performance-contingent reward conditions; however, they were instructed that they would be given two Hershey's Kisses for simply *playing* the game, regardless of their score.

The scoreboard for children of both age groups in the social-comparison information conditions displayed the scores of same-age others: children in the relative incompetency condition were shown a scoreboard indicating that most of the other children had obtained a score of 7 out of the maximum 8, whereas some of the others had scored 6 or 8; children in the relative competency condition were shown a scoreboard indicating that most of the others had obtained a score of 1 out of the maximum 8, while some of the others had scored 0 or 2. Children in the control condition were simply told that when they completed the task, they could put their score under the number on the board indicating on how many pages they found the particular figure they had been instructed to circle.

After the experimenter was confident that the children understood all aspects of the task and after the children had been given the choice of whether or not to play the game, they turned on the recorder and began the task. (One fourth-grade boy in the control condition stated that he preferred not to play the target game, and his data were excluded from the analyses.) To make performance level comparable across age groups, the actual difficulty of the task increased with grade level, so that all children obtained a score of 4 (excluding one third-grade and one fourth-grade boy, whose data were excluded from the analyses). After tabulating their scores and indicating to the children the hidden pictures on each of the pages, all children except those in the control group received the reward and put their scores on the appropriate scoreboard.

The experimenter then told the children that she had another task for them to do but needed some time to prepare the task. The children were told that they could play with any of the games that were on the table during the 5–10 minute waiting period. The alternative games, which had been pretested for their interest value, were: marbles, crayons with a game that involved following the lines to complete a picture, two mazes, and an additional set of hidden pictures. Although the same tasks were used for the two age groups, the difficulty level of the tasks was matched to age level. After the experimenter placed the tape in the recorder that corresponded to the additional set of embedded figures tasks, she stressed that the children should feel free to play with any of the toys on the table and made the children aware that they would not be given any further candy. The experimenter then went to the back room, unobtrusively watched through a one-way mirror, and recorded the amount of time during a 6-minute interval that each of the children spent with the target activity.

Results

Following the procedure of previous research (Greene & Lepper, 1974; Lepper et

Table 1
Transformed Percent of Time Spent Playing With Target Task

Reward group	Social comparison condition: Others better (indicating incompetence)	Others worse (indicating competence)	No information
	Younger children

Control			.49 (.68)

Note. Raw percentiles appear in parentheses.

al., 1973), a log transformation, $Y = \log [Y + 1]$, on the proportion of time subjects spent with the target task was performed to produce homogeneity of variance (Winer, 1971, p. 400). The major hypotheses of the study were examined by a 2 (Nursery/Elementary School Children) × 2 (Performance-Contingent Reward/Task-Contingent Reward) × 3 (Relative Competence/Relative Incompetence/No Information Regarding Competence) analysis of variance on the data. These means are presented in Table 1.

The results concerning the undermining effect of reward were expected to be revealed in two comparisons. First, it was predicted that subsequent interest in the task would be greater when the reward was made contingent on meeting a performance standard than when reward was made contingent on mere task engagement. As expected, the main effect of contingency was significant, $F(1, 111) = 4.45$, $p < .05$. However, this effect was primarily due to the data of the younger subjects, as described below in the within-grade analyses and as shown in Table 1. Additional analyses between the combined control groups and the contingency conditions revealed that interest was undermined only in the task-contingent conditions, as predicted, $t(130) = 2.0$, $p < .05$; $t(130) = 1.16$, *ns*, for task-contingent and performance-contingent groups, respectively.

The second major prediction concerned the competency information. As expected, a significant Grade × Social Comparison interaction, $F(2, 111) = 3.28$, $p < .05$, showed that relative competency information affected the subsequent interest of the older but not the younger children. Within-grade analyses were performed to examine further the pattern of data obtained. The analyses indicated that for the younger age group, reward made contingent on task engagement produced less interest in the task- than performance-contingent reward, as expected, $F(1, 53) = 4.45$, $p < .05$. Contrasts between the control and the combined contingency conditions indicated that only task-contingent reward undermined interest for the nursery-school-aged children, $t(130) = 2.67$, $p < .01$; $t(130) = 1.31$, *ns*, task- and performance-contingent reward groups, respectively. Moreover, comparative information had no effect on their later interest in the task, as expected, $F(2, 53) < 1$.

The data pattern for the older children differed sharply from that of the younger age group. For this group, intrinsic interest differed as a function of the comparative information in the predicted direction, $F(2, 57) = 5.61$, $p < .01$. Children given information about their comparatively excellent performance showed more interest in the target task than those who thought they performed worse than others, $t(57) = 3.33$, $p < .01$, or than children who had been given no information regarding performance relative to others, $t(57) = 2.33$, $p < .05$. However, contingency

Table 2
Performance as a Function of Age Level and Condition

Reward group	Social comparison condition: Others better (indicating incompetence)	Others worse (indicating competence)	No information
	Younger children		
Performance contingent	10.9	12.9	10.6
Task contingent	12.2	11.8	9.8
Control			11.3
	Older children		
Performance contingent	12.0	11.6	11.4
Task contingent	10.9	8.6	11.2
Control			11.2

of reward did not independently affect level of interest or interact with the comparative information, both Fs < 1. A specific test of the overjustification hypothesis by comparing task-contingent reward with the control did produce the expected undermining effect of reward on interest for this age group only when *no* information regarding competency was provided, $t(130) = 2.17$, $p < .05$. Furthermore, information regarding relative incompetence was found to decrease interest relative to the control, as predicted, $t(130) = 2.13$, $p < .05$. Intrinsic interest was sustained, as can be seen in Table 1, only when subjects were given information that they were relatively competent or that they had met an absolute standard of competency when no relative information was provided.

Since advocates of competing response theory have argued that performance differences resulting from distraction in anticipation of reward can explain overjustification studies(e.g., Reiss & Sushinsky, 1975; 1976), analyses were performed to test the viability of this alternative explanation for the present data. A 2 (Grade) $\times$ 7 (Condition) analysis of variance on the children's overall level of performance did not show a main effect of condition or grade nor a significant interaction, all Fs < 1. The means for the performance level of children as a function of grade and condition can be seen in Table 2. Within-cell correlations between performance level and time spent at the target task were not significant. Thus, the competing response hypothesis appears unable to provide a satisfactory account of the present data, since no differences in level of performance were found.

Discussion

The results of the present study provide support for the hypothesized effect of different types of competency information on intrinsic interest. The current experiment demonstrated that reward based on successfully meeting an absolute performance standard did not undermine interest, thereby replicating previous research (Karniol & Ross, 1977). However, when more direct information regarding competency was presented by means of social comparison, the pattern of results obtained depended on developmental level.

Consistent with previous developmental findings (e.g., Veroff, 1969; Ruble et al., in press) and with present predictions, competence information sustained the intrinsic interest of the preschool children when it was presented in terms of an absolute but not a relative standard. In contrast, although the older children were not impervious to the absolute standard indicating competence, the differential social comparison information superseded the reward contingency in its effect on subsequent interest for this age group. Specifically, task-contingent reward decreased interest relative to the control only when no information about relative compe-

tency was provided or when the comparative information indicated relative incompetence. Task-contingent reward did not produce diminished interest in the older children, as it had in the younger children, when information could be gleaned about their comparative excellence.

Thus, these results provide strong support for the competency hypothesis by showing that social comparison, providing highly direct and unambiguous information about level of competence, superseded reward contingency in its effect on intrinsic interest in older children. Furthermore, when social comparison was not provided or was not used (i.e., by the younger children) the contingency of the reward upon absolute performance level (a different kind of competence information) had the predicted effect upon later interest.

The developmental findings in the present study are relevant to recent hypotheses about the effect of rewards on intrinsic interest in children. First, they do not support Harter's (1978) hypothesis that the presentation of extrinsic incentives undermines intrinsic interest less at earlier developmental stages than at later stages. Second, the present data suggest important qualifications to Arkes' (1978) argument that young children's use of the competence but not attribution principles (e.g., discounting) renders an attributional explanation of overjustification less plausible and makes the former principle the key factor in overjustification research. While the importance of the competence principle is obviously not disputed here, our findings demonstrate that young children are not affected by certain types of competency information, in contrast to Arkes' suggestions. Moreover, the present findings suggest that the type of information that will most effectively sustain interest in children depends on the developmental level of the child.

The present results are also relevant to interpreting the findings of previous research examining the relationship between information regarding competence and the effects of rewards on intrinsic interest. First, it appears that Greene and Lepper's (1974) failure to support the competency hypothesis was probably due to their attempt to manipulate preschooler's perceptions of competence by means of social comparison information. Second, it appears that some important aspects of the competency hypothesis were obscured in the study by Karniol and Ross (1977), since they grouped children varying in age from 4 to 9 years and conveyed information about competence by varying absolute and relative standards simultaneously. Specifically, although the older children's intrinsic interest may have been influenced by both the absolute and relative information provided, the younger children may have focused on the absolute standard and may have been unaffected by the relative information.

The mediating factor assumed to account for the present findings is differential perceptions of competence resulting from information in the various competency conditions. Perceptions of competence were not assessed here, however, because they would have been contaminated by the behavioral measure or, if taken before the behavior, would have potentially confounded this measure. Nevertheless, several lines of previous research provide support for the mediating variable hypothesized here. First, a number of studies have demonstrated that information regarding absolute and relative level of performance affects children's perceptions of competence in the manner suggested here (Ruble et al., 1976; in press). Second, a considerable amount of research in the achievement literature has demonstrated a relationship between perceived competence and various task-approach indices, including persistence (cf. Ruble & Boggiano, in press; Weiner, 1974; in press). Thus, both of the mediating links necessary to support the competency hypothesis (i.e., information → self-reported competence, and competence → persistence) are well demonstrated in previous related studies.

In summary, the results of the present study provide the strongest support to date for the hypothesis that information about competence can mitigate the undermining effect of reward on intrinsic interest. The availability of direct information regarding competence presented by means of social comparison appeared to override completely the effect of

reward on behavior. This finding raises the intriguing issue of the link between overjustification phenomena and the standard achievement motivation literature, as noted by several investigators (e.g., Deci & Porac, 1978; Lepper & Greene, 1978). Research is presently underway to explore the nature of this link.

The Role of Social Comparison in Choice Shifts

George R. Goethals
Williams College

Mark P. Zanna
University of Waterloo, Waterloo, Canada

Research was conducted to test social comparison predictions regarding influence processes related to risk taking in groups. It was shown that shifts toward risk were as likely to occur in groups where subjects exchanged information about their positions on the Kogan and Wallach Choice Dilemma Questionnaire (CDQ) *and* information about their self-ratings of ability as in ordinary group discussions of the CDQ items. Subjects in groups where only information about CDQ positions was exchanged showed far fewer shifts to risk. These findings are discussed in terms of a social comparison analysis of the social influence processes involved in risky shifts, which assumes that comparison processes can be engaged fully only when comparability is established by knowledge of other group members' standing on traits thought to be related to risk taking.

In a comprehensive review of the risky shift literature, Dion, Baron, and Miller (1970) suggested that the existing research seemed to lend more support to Brown's (1965) "risk as a value" explanation of the risky shift than to accounts emphasizing diffusion of responsibility, leadership, or familiarization. However, Dion et al. noted that the existing data did not seem to offer strong support for the social comparison mechanism that was implicit in Brown's argument. Subsequently, Burnstein and Vinokur (cf. Burnstein & Vinokur, 1975, 1977; Burnstein, Vinokur, & Trope, 1973) proposed an alternative "persuasive arguments" version of the risk as a value idea. This account holds that subjects discussing the items in the Kogan and Wallach (1964) Choice Dilemma Questionnaire (CDQ) have available a preponderance of arguments favoring risk, presumably because risk is a cultural value. As a result of this preponderance of arguments, in any discussion about the CDQ items, subjects are likely to encounter more good arguments favoring risk that they had not considered before than arguments favoring caution. These arguments are likely to persuade subjects and produce genuine attitude change in the direction of increased risk.

Burnstein and Vinokur (1975) did acknowledge a "few embarrassing studies" that produced an effect constituting a "puzzle for the persuasive-arguments explanation" of the risky shift. These were the studies showing that a shift was sometimes produced when subjects were simply given information about others' positions (e.g., Teger & Pruitt, 1967). The explanation for these studies seemed to be social comparison, that is, that subjects shifted when they discovered the positions of other people, because they learned that they themselves were not as risky as they had imagined relative to others, and they wanted to correct that state of affairs by shifting. Although this effect has not been consistently obtained,[1] it did suggest that a shift could sometimes be produced without discus-

The authors thank Joan Hall, Thomas Martin, Linda McKend, Sandra Ryan, and Betsy Zanna for their help in collecting and analyzing the data, and John Holmes, David Myers, and Neil Vidmar for comments on an earlier draft of the manuscript.

[1] Pruitt (1971a, 1971b, has cited several articles that have included one or more information exchange conditions. It is important to note that of the 13 replications only 4 actually resulted in significant risky shifts.

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3709-1469$00.75

sion and therefore without opportunity for argumentation. However, Burnstein and Vinokur suggested that persuasion could account for even those shifts obtained without discussion. Their rationale was that knowledge of other people's positions inspires a self-generation of reasons for those positions. It is these reasons, not comparison pressures, that produce the shift. Burnstein and Vinokur argued, then, that persuasion was necessary and sufficient to account for all risky shifts. (This position has been disputed in reviews of the literature that are not necessarily sympathetic to social comparison theory, cf. Myers & Lamm, 1976. Also, Baron & Roper, 1976, have questioned whether Burnstein and Vinokur's 1975 data unequivocally support the self-generation of arguments idea.)

Recently, however, two new lines of research have been reported that revitalize the social comparison account of the risky shift. Blascovitch and his colleagues (Blascovitch & Ginsburg, 1973; Blascovitch, Ginsburg, & Veach, 1975) have conducted several studies showing shifts toward risk in groups placing bets in blackjack games in gambling establishments in the state of Nevada. They argued for a social comparison explanation for their findings. Baron and his colleagues (Baron & Roper, 1976; Sanders & Baron, 1977) have also proposed an account of risky shifts involving social comparison. This view holds that subjects want to be as risky as other group members or slightly more so because risk is a value, and that there is a tendency for the group as a whole to shift toward risk as a result of this desire. Countervailing values for being sensible or not reckless presumably place some kind of limit on this competition to be relatively risky. The most recent exposition of this approach, that of Sanders and Baron (1977), argues that social comparison plays a large but not exclusive role in choice shifts. They believe that both social comparison and persuasion operate to produce risky shifts and that neither is capable of accounting for all the data. They suggest that the two processes are not mutually exclusive and may even be complementary. For example, it is possible that subjects are receptive to arguments favoring risk that emerge in group discussion because such arguments justify a shift toward risk that they want to make because of social comparison concerns. The arguments can provide a justification for opinion changes that subjects want to make anyway.

The purpose of the present paper is to discuss several studies designed to explore more thoroughly the role of social comparison processes in choice shifts. The starting point for these investigations was Goethals and Darley's (1977) recent restatement of Festinger's (1954) social comparison theory within an attribution theory framework. Their formulation suggests that people will compare their opinions with others who should have similar opinions, given their standing on attributes related to and predictive of those opinions, and that people will feel that they have selected appropriate opinion positions if people who are similar on these attributes agree. A recent experiment by Zanna, Goethals, & Hill (1975) supports this analysis by showing that subjects do compare with others who are similar on related attributes.

What kind of attributes do people feel are related to risk taking? A study by Jellison and Riskind (1970) suggested that ability is perceived as related to risk. They contended, in fact, that risk is a cultural value, as Brown (1965) and others had suggested, because of its link with ability. Risk and ability are linked in that the probability that a person will succeed if he engages in a risky behavior is directly dependent on his ability—the more ability, the more probable success. Given the risk–ability link, social comparison theory implies that people will feel it is appropriate to take as much risk as others of equal ability but less risk than those who possess greater ability.

In order to test this reasoning, one initial and two follow-up experiments were conducted in which subjects were given information indicating that others of either extremely high or moderate ability had recommended a high degree of risk on CDQ items. It was predicted that subjects would feel comparable to others of moderate ability and would want to move toward risk themselves when exposed

to their risky recommendations, but would cease comparison with the superior-stimulus persons and would not be influenced by their risky recommendations. The first experiment was only partially successful. In neither experimental condition did subjects' recommendations differ significantly from those in a control, nor did they differ from each other. However, manipulation check data showed that many subjects in the high-ability conditions perceived themselves to be equal in ability to the stimulus persons. An internal analysis was performed where subjects were assigned to one of three groups depending on whether they had indicated on the manipulation check that they saw the stimulus persons as having more, less, or equal ability compared to themselves. Subjects in the group perceiving themselves as equal to the stimulus persons were more risky than subjects in the control condition and more risky than those who perceived the stimulus persons to have more ability. This finding suggests that being influenced toward risk in a group is dependent on a perception of similarity and comparability on the dimension of ability and on social comparison tendencies being fully engaged as a consequence.

This conclusion, however, is clearly an extrapolation from the data and is only supported by an internal analysis. Consequently two replications were conducted in which great emphasis was placed on embellishing the high-ability manipulations so that it would be impossible for the subjects to perceive themselves as being even remotely as talented as the stimulus persons. Unfortunately, the results for both replications were very similar to the results of the initial experiment. As in the initial study, many subjects perceived the stimulus persons in the high-ability conditions to be equal in ability to themselves, and in each case an internal analysis was performed. For both follow-up studies this analysis indicated, as before, that subjects shifted to risk more when they perceived the stimulus persons to be equal in ability than when they perceived the stimulus persons to be more able, and that only in the equal ability group was there a significant shift to risk.

Given the limited success of these experiments, a new approach was devised to test more directly the hypothesis that the extent to which groups will shift to risk is dependent on the extent to which social comparison tendencies are fully engaged in those groups. This approach grew out of the previously discussed finding that experimental procedures using information exchange, where subjects are given information about other group members' CDQ positions but not their reasons for adopting those positions, show shifts of lesser magnitude than those found following full discussions of CDQ items. These data suggest that social comparison is not sufficient to account for large choice shifts following group discussion and that persuasive arguments are needed fully to influence group members toward risk. How can these studies be reconciled with a social comparison analysis of choice shifts? The key would seem to be a careful consideration of what is and what is not exchanged in information exchange experiments.

The three experiments reported above suggest that ability information interacts with information about the stimulus person's positions on CDQ items and that for social comparison processes to operate fully in a group discussing risk, the group members need to know more than the other members' recommendations regarding risk; they need to have information about others' abilities as well. It seems reasonable to argue, then, that the traditional information exchange studies may not fully engage social comparison because they fail to give subjects ability information that is critical in making any comparison of recommendations regarding risk meaningful. That is, because subjects have no information about the group members' abilities, their recommendations regarding risk have ambiguous implications for the level of risk that is appropriate for the subject to recommend. Hence, we should not expect consistent shifts in traditional information exchange conditions (see Footnote 1).

Suppose subjects were placed in an information exchange situation where information about both position and ability is being conveyed. If each person in the group indicates

that he believes himself to be somewhat more able than the average person, as one might expect from Jellison and Riskind's (1970) results, then each person in the group should come to feel that other group members are comparable to themselves on the relevant background characteristic, ability (i.e., they are all "above average"). Social comparison should be fully engaged, and we should expect risky shifts of greater magnitude to occur.

But will shifts in the more complete information exchange condition be as large as those that result from group discussion? If the result of group discussion, in addition to exchange of information concerning position, is primarily exchange of information concerning ability, then our answer would be yes. If relevant arguments make a difference over and above the reassessment due to social comparison, however, then our answer would be no. At any rate, the purpose of our experiment is to give social comparison theory a fair test; the prediction is that a more complete information exchange condition will produce a shift toward risk of greater magnitude than a "traditional" information exchange condition. Whether the shift in this new information exchange condition will be as large as that following a group discussion is, for us, an empirical question.

Method

Subjects

Two replications of the experiment were conducted. In one replication, conducted at Rider College (Trenton, New Jersey), 38 male and 26 female summer students served as subjects; in the other replication, conducted at the University of Waterloo, 73 female students participated. In each case, care was taken to assure that the subjects participating in a given group were not close acquaintances. In the Rider replication each subject was paid for his or her participation; in the Waterloo replication, subjects were drawn from a voluntary subject pool associated with their introductory psychology course.

Procedure

Subjects were run in groups of four, except for nine groups in the Waterloo replication, which contained five subjects. Each group was composed of subjects of the same sex who did not know each other well. Four groups of subjects were run in each experimental condition in each replication.[2] The experimenter began by explaining that the study was concerned with decision making. He or she then described the nature of the choice dilemma problems, giving subjects a sample problem (the football captain). Next he or she asked subjects to read, think about, and answer the same four choice dilemmas as employed in the initial experiment (items dealing with the prospective chemistry graduate student, the prospective concert pianist, the businessman considering running for political office, and the research physicist). After subjects had given their initial responses (and the booklets had been collected), they were asked to fill out an anonymous background questionnaire that asked, "Compared to the average person of your age and sex, rate yourself in terms of your overall talent, creativity, and ability" (answered on a 7-point scale with points labeled "a great deal above [below] the average," scored 7 and 1, respectively, "moderately above [below] the average," "slightly above [below] the average," and "just at the average," scored 4).

Group discussion condition. At this point the procedures for the three experimental conditions diverged. Calibrating the time parameters employed by Teger and Pruitt (1967), subjects in the group discussion condition were given 30 minutes to discuss the set of four choice dilemmas. New booklets containing the problems were handed out to facilitate these discussions.

Information exchange of position condition. This condition closely resembled that conducted by Teger and Pruitt (1967). In addition to the new booklets of choice dilemmas, subjects were given a set of cards indicating the various odds depicted in the choice dilemma problems and were asked merely to indicate their current positions by holding up the appropriate card. In this condition each subject in turn indicated his or her current position three times for each problem.

Information exchange of position and ability condition. This condition resembled the previous information exchange condition except that subjects were also handed a set of cards that matched the alternative answers to the question for which they rated their own ability. Just prior to indicating their positions for the first time on the first choice dilemma, subjects were asked, again in turn, to indicate their answers to the ability question. In the Waterloo replication subjects were asked to indicate their ability positions again after the second of the four choice dilemmas. No talking was allowed in either information exchange condition.

Control condition. Subjects in the control condition were given only 10 minutes to reconsider their

[2] Actually, in the Rider replication, subjects in the control condition were run in groups of size 2, 3, or 4. For purposes of analysis subjects were randomly assigned to four groups of size 4.

recommendation. No information whatsoever about others' responses was provided.

In the Rider replication, subjects in all conditions were asked to make their final private recommendations after the entire discussion, information exchange, or reconsideration phase; in the Waterloo replication, final judgments were made after each item was processed. Finally, subjects were debriefed and, in the Rider replication, were paid for their participation.

Results

Preliminary analyses indicated no significant effect of sex of subject or interaction of sex with experimental conditions within the Rider replication; hence, data were collapsed across this dimension within this replication. In addition, preliminary analyses indicated no significant effect of replication or interaction of replication with experimental conditions; hence, data were also collapsed across this dimension.

Ratings of Ability

As expected subjects did rate themselves as more able than "the average person of (their) age and sex." The overall mean on the scale, which ranged from "a great deal below the average," scored 1, to "a great deal above the average," scored 7, was 5.36. Twelve subjects (or 9%) felt they were "a great deal above," 51 (or 37%) felt they were "moderately above," 50 (or 36%) felt they were "slightly above," and only 23 (or 17%) felt they were "just at the average." One subject in the sample (or 1%) felt he was "moderately below average." This distribution was similar for each condition.

Postmanipulation Shifts

A preliminary analysis indicated that the variation in the magnitude of shifts was considerably greater in the group discussion condition whether the unit of analysis was the group ($F_{max} = 28.15$, $p < .01$) or the individual subject ($F_{max} = 6.82$, $p < .001$).[3] Therefore, to best describe the data the primary analyses are nonparametric in nature.

Table 1 presents the number of groups in which more subjects shifted in the risky than in the cautious direction and the number of groups in which an equal or greater number shifted in the cautious direction. The overall chi-square analysis indicates that the treatment effect is highly reliable, $\chi^2(3) = 10.42$, $p < .02$. As can be seen in Table 1, this overall effect is primarily due to the fact that a greater proportion of groups in the group discussion and information exchange of position and ability conditions (81% combined) had more subjects shifting to risk than to caution; this percentage contrasts with that for the information exchange of position and control conditions (25% combined), $\chi^2(1) = 8.03$, $p < .01$; Yates' correction for continuity was applied to this statistic. This difference accounts for 97.5% of the overall differences among the four conditions. Individual comparisons indicated that (a) the proportion of groups with more shifts to risk than caution was not reliably greater in the group discussion condition than in either the information exchange of position condition or the control condition ($p = .13$, in each case, by Fisher's exact test) but (b) the proportion of groups with more shifts to risk than caution was significantly greater in the information exchange of position and ability condition than in either the information exchange of position condition or the control condition ($p < .05$, in each case, by Fisher's exact test). Finally, there was no difference between the group discussion and information exchange of position and ability conditions.[4]

---

[3] The direct comparisons of variances between the group discussion and the information exchange of position and ability conditions were highly reliable in both cases, $F(7, 7) = 15.28$, $p < .001$, and $F(34, 34) = 6.82$, $p < .001$, for the by-group and by-individual subject analyses, respectively.

[4] There are other possible nonparametric analyses. One could consider the total number of subjects who shifted to risk or caution or who did not change. As in the analysis above, a virtually identical proportion of subjects shifted to risk in the group discussion and exchange of position and ability conditions (59% combined), and a virtually identical proportion shifted to risk in the exchange of position and control conditions (36% combined). These proportions differ significantly, ($\chi^2(1) = 6.22$, $p < .02$. Another approach is to consider the proportion of groups shifting to risk, using as the criterion whether the final mean score of the subjects in a group is

Table 1
Number of Groups in Which More Subjects Did or Did Not Shift to Risk Than to Caution

Direction in which subjects in groups shifted	Experimental condition			
	Group discussion	Information exchange of position and ability	Information exchange of position	Control
More to risk than caution	6	7	2	2
The same or more to caution	2	1	6	6

Discussion

The central hypothesis of the present study was that there would be more shifts to risk resulting from exchanging information on CDQ items if subjects also exchanged information that could establish that they were similar on attributes related to risk taking. This hypothesis was confirmed. It is interesting to recall (see footnote 1) that information exchange experiments have yielded highly inconsistent data. Sometimes they produce a risky shift; sometimes not. It could be that whether or not a shift occurs depends on the degree to which subjects can infer important unknowns about the other person's position on related attributes. If they know absolutely nothing about the other persons, then little comparability can be assumed and no choice shift should follow information exchange. If, on the other hand, subjects are familiar with each other and similar levels of ability can be assumed, then social comparison will be more strongly engaged and a choice shift is more likely to follow.

The results support the general proposition that social comparison on a particular attribute is only meaningful when something is known about how you and the others should compare on that attribute, given your relative standings on related attributes. This point can easily be seen in many instances of opinion formation and change. Whenever a person expresses an opinion on any issue, the meaning of that expression must be interpreted in terms of that person's identity and his standing on various related attributes. An American congressman appraises the president's performance. We would like to know to what political party he belongs. A Canadian citizen signs a petition opposing confederation. We would like to know whether the person is a Francophone or Anglophone and in what province he or she lives. The point is equally true with ability comparison. A person has just run the hundred-yard dash in 11 seconds. How old was the person? Male or female? What kind of coaching, equipment, and so forth, was made available to the person? What were the track and weather conditions? The meaning of another's opinion or performance can only be calibrated by knowing the person's standing on related attributes. Knowledge of environmental factors might also be necessary in many instances.

How, then, do present findings relate to the controversy in the literature regarding the various explanations for the risky shift and other choice shifts? The present results show that when information about one's self-estimate of ability and one's recommendations about risk are exchanged, groups shift as often toward risk as they do following group discussion. The mechanism producing the shift in the information exchange of position

riskier or more cautious than the mean of their initial scores. The proportion of groups shifting to risk is 75% in both the group discussion and exchange of position and ability conditions. The proportion of groups shifting to risk is 50% in both the exchange of position and control conditions. With the small number of groups, these proportions do not differ significantly. Overall, however, the findings from these analyses are similar to those from the analysis above.

and ability condition cannot be persuasion. There is no argumentation in this condition. Even if one accepted a self-generation-of-arguments explanation of those studies where information exchange of position has produced a risky shift, it is difficult to see how such an explanation could account for the clear difference between the two information exchange conditions reported here.

While it seems clear that social comparison produces the shift in the information exchange of position and ability condition, there is considerable doubt as to what is producing the risky shift in the group discussion condition. This uncertainty is not new. There has for many years been doubt about the cause of the shift in that condition. It seems that the answer would well be social comparison. The same kind of social comparison that is engaged in our exchange of position and ability condition could occur in the group discussion condition. Through discussion, participants could quickly see that the others were socially comparable. In order to explore the possibility that subjects would come to view their fellow group members as more able (and thus more similar to themselves in ability) following group discussion, subjects in the experimental conditions were asked at the very end of the experiment to indicate how they felt about each person in their group "in terms of his (or her) overall talent, creativity, and ability" (using same 7-point scale on which they had previously indicated their own ability). In the information exchange of position condition, subjects in 6 (of the 8) groups, on the average, believed they were at least a third of a unit more able than the "average" group member; in contrast, this was the case in only 3 groups in the information exchange of position and ability condition and in only 1 group in the group discussion condition, $\chi^2(2) = 6.51$, $p < .05$. The difference between the group discussion and the information exchange of position conditions, which is reliable at the 5% level by Fisher's exact test, indicates that group discussion apparently did lead subjects to think more highly of their fellow group members. Moreover, there was a relationship between the perceived ability of the "average" group member and risk taking. Of the 10 groups feeling that fellow group members were at least one-third of a unit less able than they themselves, only 5 had more subjects shifting in the risky than in the cautious direction, 1 had an equal number of risky and cautious shifters, and 4 had more subjects shifting in the cautious than in the risky direction; of the remaining 14 groups, who essentially saw others as similar in ability, 10 had more subjects shifting in the risky than in the cautious direction, 4 had equal numbers of risky and cautious shifters, and no group had more subjects shifting in the cautious direction, $\chi^2(2) = 6.97$, $p < .05$. (It might be noted that the one group in the group discussion condition, which for some reason did not come to believe that fellow group members were basically similar in ability, was the only group in that condition that had more cautious than risky shifters.)

In arguing favorably concerning a social comparison analysis of the risky shift, we do not mean to imply that persuasion does not occur or that it does not occur in groups discussing risk. The processes of persuasion and comparison, again, are not mutually exclusive. Many things happen in group discussions. That both comparison and persuasion are occurring at the same time, in different amounts for different individuals, seems perfectly plausible. The goal of the present research has not been to rule out persuasion. It has simply been to show that influence produced by social comparison can be substantial but that social comparison is not fully engaged unless particular kinds of important information are made available to subjects, making the fact of comparability evident to them. Once comparability has been appropriately established, comparison can produce opinion shifts of the magnitude found in studies of the risky shift. In real life, discussion may be necessary to establish comparability. The present study shows, however, that even if comparability is established by other means, similar opinion shifts occur.

Some Child-Rearing Antecedents of Criminal Behavior in Adult Men

Joan McCord
Department of Psychology and Sociology, Drexel University

Records collected during childhood and coded prior to knowledge of adult behavior provided information about the childhood homes of 201 men. Thirty years later, information about criminal behavior was collected from court records. Multiple regression and discriminant function analyses indicate that six variables describing family atmosphere during childhood—mother's self-confidence, father's deviance, parental aggressiveness, maternal affection, parental conflict, and supervision—have an important impact on subsequent behavior.

Despite a massive literature emphasizing the importance of child rearing, conscientious critics (e.g., Clarke & Clarke, 1976; Yarrow, Campbell, & Burton, 1968) have raised legitimate doubts regarding the impact of parental behavior on personality development. Many of the studies that link parental behavior with personality development rely upon a single source of information for both sets of variables; systematic reporting biases could thus cause obtained relationships. Most of the remaining studies have depended upon concurrent measurements, leaving doubt as to the direction of influence between parents' behavior and characteristics of the child. Questions about interpreting the results of both types of studies serve to highlight the importance of longitudinal research.

A few researchers have gathered information through longitudinal studies, using independent sources for measuring child rearing and for measuring personality. Robins (1966) analyzed information from clinic records gathered during childhood and related that information to data gathered when the subjects were adults. Robins pioneered assessment of long-term effects of child rearing, and her study raises doubts about the validity of retrospective reports on family socialization. Nevertheless, since predictor models combined variables describing child rearing with other types of variables (empirically linked with outcome), the research fails to provide convincing evidence that child-rearing differences affected adult behavior.

Block (1971) evaluated character development among subjects in the Berkeley longitudinal studies. Dividing 63 subjects into five types and checking differences in their backgrounds, Block reached the conclusion: "What comes through, for both sexes and without exception in viewing the various types, is an unequivocal relationship between the family atmosphere in which a child grew up and his later character structure" (p. 258). Although Block reports many statistically reliable differences, his analyses do not permit the reader to evaluate the strength of relationships between family atmosphere and character structure.

In 1973-1974, Werner and Smith (1977) retraced 88% of the children born on Kauai Island in 1955. Interviews with the mothers provided evidence about the family environ-

This study was supported by U.S. Public Health Service Research Grant 2 RO1 MH26779, National Institute of Mental Health (Center for Studies of Crime and Delinquency). It was conducted jointly with the Department of Probation of the Commonwealth of Massachusetts. The author wishes to express appreciation to the Division of Criminal Justice Services of the State of New York and to the Maine State Bureau of Identification for supplemental data from criminal records, though they are responsible neither for the statistical analyses nor for the conclusions drawn from this research.

ment of subjects when they were newborn infants, age 2, and age 10. Although combined measures tended to account for a relatively high proportion of variance in several problem areas, the authors did not assess specific child-rearing models as predictors of outcome behavior.

Lefkowitz, Eron, Walder, and Huesmann (1977) used a main effects model in stepwise multiple regression for their longitudinal study of aggression. Only two of the six variables that together accounted for about a quarter of the variance in male aggressiveness at age 18 were related to child rearing at age 8. Since the model included both redundant measures of child rearing and heterogeneous variables (e.g., child's preference for girls' games, parents' religiosity, and ethnicity of family), effects of differences in child rearing may have been masked by collinearity (Blalock, 1963; Gordon, 1968; Mosteller & Tukey, 1977).

The paucity of evidence to support a view that child rearing affects personality has led some authors (e.g., Clinard, 1974; Jessor & Jessor, 1977) to the conclusion that home atmosphere during childhood has a negligible effect upon personality development. Such authors present the challenge to which the present research is addressed: if parental behavior has an important impact upon personality development, differences in child rearing ought to contribute to variations in subsequent behavior.

Method

Subjects for this study were selected from a treatment program designed to prevent delinquency. The youths ranged in age, at the time of their introduction to the program, from 5 to 13 ($M = 10.5$, $SD = 1.6$).

Counselors visited 253 boys twice a month, for an average 5-year period between 1939 and 1945. With the exception of one who was a nurse, the counselors had been trained as social workers. After each visit, the counselor recorded observations about the family as well as the child.[1]

Case records from the treatment program described, in detail, whatever activities the counselors had observed on their visits to the homes. The records included reports of conversations with parents, friends, neighbors, and teachers as well as with the boys. Counselor turnover (a potential problem from a treatment perspective) produced a benefit for research: most of the families were visited by more than one counselor.

To justify treatment of family backgrounds as independent units for analyses, only one subject from a family was included. Boys not reared by their natural mothers were also excluded. After eliminating brothers ($n = 21$) and those not reared by their natural mothers ($n = 36$), 201 cases remained for analysis.[2]

In 1957, coders read each case thoroughly in order to form judgments about the home and family interaction. These coders had no access to information about the subjects other than that contained in treatment records. A 10% random sample of the records was read independently by a second coder to yield an estimate of the reliability of the coding.[3] Variables from the coded case records were used in the present study.

The mother's attitude toward her son had been classified as actively affectionate (if there had been considerable interaction, without continual criticism, between mother and child, $n = 95$), passively affectionate (if there had been little interaction between mother and son, though the mother had shown concern for her child's welfare, $n = 51$), ambivalent or passively rejecting (if there had been marked alternations in the mother's attitude toward her son so that she had seemed sometimes to be actively affectionate and sometimes rejecting, or if the mother had seemed unconcerned about the child's welfare, $n = 43$), or actively rejecting (if the mother had appeared to be constantly critical of the boy, $n = 11$). Independent reading of 25 cases resulted in the same ratings for 80%.

Two ratings from the original codes were combined to evaluate effects of supervision. One described whether the child's activities outside of school were governed by an adult. This scale was divided to indicate whether supervision was generally present, occasionally present, or absent. Independent coding yielded identical ratings for 84% of the 25 randomly selected cases. The second rating described parental expectations regarding the boys' activities. Coders were instructed to rate expectations as "high" if the

---

[1] The project included a matched control group. Since records on family life, for the control group, were limited to information gathered during the intake interviews supplemented by information from secondary sources, the control group was not used in this study. Originally, 325 boys were included in both the treatment group and the control group. By January 1942, 253 boys remained in each group. (See Powers and Witmer, 1951, for details regarding selection of cases and a description of the treatment program.)

[2] The criteria are not mutually exclusive. Five men were eliminated through both of the selection criteria.

[3] See McCord and McCord (1960) for a complete description of the coding.

child was given responsibility for care of his younger siblings, for preparation of meals, for contributing to the financial support of the family, or for doing "extremely well" in school. Independent ratings yielded agreement for 76% of 25 cases. The scales from the 1957 codes were combined to classify subjects into one of four categories: supervision generally present and high expectations for the child to accept responsibilities ($n = 40$), supervision generally present without evidence that high expectations were placed on the child ($n = 78$), occasional supervision ($n = 60$), and supervision absent ($n = 23$).[4]

A rating of parental conflict was based on counselors' reports of disagreements between the parents. Raters were instructed to look for conflicts about the child and conflicts about values, about money, about alcohol, and about religion. Parental conflict was coded into one of four categories: no indication, apparently none, some, or considerable. For the present research, cases were divided into those whose parents evidenced considerable conflict ($n = 68$) and those coded in alternative categories. Independent readers agreed, for this division, on 80% of the cases checked for reliability.

Three measures from the 1957 codes were combined to identify aggressive parents. Coders classified the aggressiveness of each parent by looking for evidence that the parent "used little restraint" when angry. Case records included reports on parents who threw things (e.g., one father threw a refrigerator down the stairs in the midst of an argument with his wife), hit people, broke windows, and shouted abuses. Independent coders agreed on 84% of the fathers and 92% of the mothers in classifying parents as aggressive. The coders described paternal discipline; the category "consistently punitive" identified fathers who regularly used physical force (e.g., beating a child) or very harsh verbal abuse. Independent coders agreed on 92% of the cases for ratings regarding this classification. If a parent was coded as aggressive or the father was coded as consistently punitive, the child was classified as having an aggressive parent ($n = 75$).[5]

The 1957 codes included a measure of the mother's self-confidence. A rating as self-confident was assigned if that mother showed signs of believing in her own abilities ($n = 55$). Other possibilities for this rating were "no indication of general attitude; evidence that mother saw herself as a victim or pawn in a world about which she could do nothing; and neutral, that is, generally seemed merely to accept things as they came." For this variable, independent raters agreed in classifying 84% of the 25 cases used to estimate reliability.

In 1957, coders rated a father as alcoholic if the case record indicated that he had lost jobs because of repeated drinking, if marital problems were attributed primarily to his excessive drinking, if welfare agencies had repeatedly pointed to the father's drinking as grounds for family problems, or if the father had received treatment specifically for alcoholism. Independent coders agreed for 96% of the ratings on this variable. In 1948, after termination of the treatment program, criminal records on the family members of subjects were collected; these records were locked in a file separate from the case histories. In 1975, after names had been replaced by numerical identifiers, an assistant unfamiliar with the case records coded these criminal records. For the present study, a father was considered "deviant" if the case record indicated that he was an alcoholic, if the criminal record showed that he had been convicted at least three times for drunkenness, or if his criminal record showed that he had been convicted for a serious crime (i.e., theft, burglary, assault, rape, attempted murder, or murder). These criteria led to identification of 86 fathers as deviant.[6]

Case records included information about family structure. A father was considered "absent" if his residence was not with the subject's mother. Independent coding of 25 cases yielded agreement on 96% regarding whether or not the boy was living with both natural parents.[7] The 71 boys having absent fathers ranged in age, at the time when the loss occurred, from birth to 16 ($M = 7.01$, $SD = 5.03$). The father-absent subjects were subclassified to identify those whose natural fathers had been present during their first 5 years ($n = 48$) and those for whom the absence had occurred prior to the age of 5 ($n = 23$).

These seven variables (mother's affection, supervision, parental conflict, parental aggression, mother's self-confidence, father's deviance, and paternal absence) were used to depict the home atmosphere of subjects during childhood. The first three are regarded as directly related to child rearing. Relationships among these measures are shown in Table 1.

Subjects had been selected from congested urban neighborhoods. Nevertheless, differences in social status could contribute to subsequent differences in behavior. Two measures of social status were available. The case records supplied information about the father's occupation. Coders classified these occupations as white-collar (9.6%), skilled tradesmen (32.8%), or unskilled workers (57.6%). The reliability check yielded agreement on 96% of the ratings. A second measure of social status was provided by a rating of the neighborhoods in which the boys were raised. These ratings had been made, in 1938 and 1939, as part of the selection procedures. The ratings took into account delinquency rates, availability of recreational facilities, and proximity to bars, railroads, and junkyards. These ratings were coded on a 4-point scale from better to worst neighborhoods. The two measures tended to covary, Cramer's $V(6) = .218$, $p = .0044$.

---

[4] Only nine boys exposed to high expectations had not been rated as generally supervised.

[5] Fifty of the subjects were classified as having aggressive parents by the direct description of parental aggression.

[6] Forty-nine had been convicted for serious crimes.

[7] Of the 86 deviant fathers, 40 were also absent fathers.

Table 1

* $p < .05$. ** $p < .01$. *** $p < .001$.

Between 1975 and 1978, the subjects were retraced. Among the 201 men included in the study, 153 (76%) were alive and in Massachusetts at least until the age of 40;[8] 16 (8%) had died prior to their 40th birthdays; 29 (14%) had migrated from Massachusetts; and 3 (1%) remained to be found.

During 1975 and 1976, the names (and pseudonyms) of all the men who had been in the program were checked through court records in Massachusetts.[9] These criminal records were traced and coded by different people from those who coded other records. Coders of the criminal records (and those who traced them) had no access to other information about the subjects. The court records showed the dates of court appearances and the crimes for which the subjects had been convicted. They were coded to show the type of crime and the age of the person when he was convicted. Convictions for serious property crimes (larceny, auto theft, breaking and entering, arson) and serious personal crimes (assault, attempted rape, rape, attempted murder, kidnapping, and murder) were used as dependent measures for this study.

Among the 201 men, 71 had been convicted for at least one serious crime; 53 had been convicted for property crimes and 34 for personal crimes (including 15 convicted for both types). Their ages when first convicted ranged from 8 to 38, with a mean of 18.7 ($SD = 8.7$) and a median of 20. Those convicted prior to their 18th birthdays were classified as juvenile delinquents ($n = 43$); those convicted after reaching the age of 18 were classified as adult criminals ($n = 48$, including 20 who had been juvenile delinquents).

After analyzing the relationship to crime of each of the childhood variables separately, multiple regression analyses (General Linear Model Procedure, Barr, Goodnight, Sall, & Helwig, 1976) were used to ascertain the contribution of child rearing to the variance in number of serious property and personal crimes. To test the degree to which knowledge of home atmosphere could enable accurate prediction of subsequent behavior, the six central variables describing home atmosphere were used in discriminant function analyses to identify criminals.

As a more stringent test of the contribution of home atmosphere to subsequent crime, the discriminant function analyses were also used to predict criminals among the subsample whose criminal records provided the most complete histories of convictions: those men living in Massachusetts at least until the age of 40. If this function identified criminality more accurately for the total group than for those living in Massachusetts, there would be grounds for suspecting an interaction effect between home background and unmeasured variables. If this function identified criminality at least as accurately for those alive in Massachusetts at the age of 40, there would be additional support for a conclusion that home atmosphere during childhood contributes to criminality.

Results

As a first step toward learning whether parental behavior contributes to subsequent differences in criminality, the seven scales describing home atmosphere and the two scales describing social status were individually analyzed for their contributions to the variance in number of serious crimes against property and persons. (See Table 2.)

With the exception of father's absence, each of the scales describing home atmosphere accounted for a statistically significant ($p < .05$) proportion of the variance in number of crimes against property, persons, or both.[10]

[8] Among them, 147 were in Massachusetts through their 45th birthdays.

[9] These records were supplemented by court records from the states of New York, Maine, Michigan, Nebraska, and Florida, where some of the men had resided.

[10] The Duncan multiple range test, modified for unequal groups (Kramer, 1956), indicated that boys without supervision, reliably ($p < .05$) more than boys in the other three categories, were convicted

Table 2

Father's occupation	2, 195	.008	0.74	.4798	.012	1.15	.3181

Neither of the measures of social status was significantly related to these types of crimes.

Supervision and mother's self-confidence were related to both crimes against property and crimes against persons; mother's affection and father's deviance were related to property crimes (though not to personal crimes); conflict and parental aggression were related to personal crimes (though not to property crimes). The boys who lacked maternal affection, who lacked supervision, whose mothers lacked self-confidence, and whose fathers were deviant were more often subsequently convicted for property crimes. The boys who lacked supervision, whose mothers lacked self-confidence, and who had been exposed to parental conflict and to aggression were subsequently more often convicted for personal crimes.

The relationships to criminality of individual variables describing home atmosphere, though statistically significant, each accounted for a relatively small proportion of the variance. More important, since "criminogenic" conditions tended to be related to one another, these relationships could not be taken as evidence that the differences in home background that they represented resulted in differences in subsequent behavior.

To evaluate the contribution of parental behavior to subsequent behavior, the six central variables describing home atmosphere were divided into two sets. The first set included those variables that described characteristics of the parents, characteristics that might be viewed as antecedent to child-rearing practices: parental aggressiveness, paternal deviance, and mother's self-confidence. The second set included the three variables that described interpersonal behavior: parental conflict, supervision, and mother's affection; these were considered to be direct measures of child rearing. The effect of this division was to classify families in two ways. The first classification took account of relationships among the variables describing the parents; the second took account of relationships among the variables describing child rearing.

Sequential multiple regression models were used. They introduced the measure of social status (the interaction of father's occupation and neighborhood) as the first variable. The regression procedure next evaluated the sequential contribution to explained variance of parental characteristics (the interaction of paternal deviance, maternal self-confidence, and parental aggression). After controlling effects of both social status and parental characteristics, the procedure evaluated effects of child rearing (i.e., the interaction of supervision, parental conflict, and the mother's affection).

Child rearing, as measured in this longitudinal study, clearly accounts for a signif-

for both property and personal crimes. This a posteriori test showed that boys rejected by their mothers were most likely to be convicted for property crimes, and boys who had affectionate mothers were least likely.

Table 3
Home Environment and Subsequent Criminality

Sequential contribution	*DF*	R^2	*F*	*PR > F*
Predicting property crimes[a]				
Social status	11	.0688	1.55	.1185
Parental characteristics	7	.0610	2.16	.0404
Child rearing	27	.2612	2.40	.0005
Predicting personal crimes[b]				
Social status	11	.0541	1.16	.3222
Parental characteristics	7	.0588	1.97	.0616
Child rearing	27	.2444	2.13	.0023
Predicting total crimes[c]				
Social status	11	.0620	1.40	.0620
Parental characteristics	7	.0691	2.45	.0209
Child rearing	27	.2601	2.39	.0005

[a] Model: $R^2 = .391$, $F(45, 151) = 2.15$, $p = .0003$. [b] Model: $R^2 = .3573$, $F(45, 151) = 1.87$, $p = .0028$. [c] Model: $R^2 = .3912$, $F(45, 151) = 2.16$, $p = .0003$.

icant proportion of the variance in subsequent criminality. Table 3 describes the decomposition of the regression models.

As predictors of property crimes, the model accounts for 39.1% of the variance, $F(45, 151) = 2.15$, $p = .0003$. Parental aggression, paternal deviance, and maternal self-confidence account for 6.1% of the variance after controlling social status, $F(7, 151) = 2.16$, $p = .0404$. Parental conflict, supervision, and maternal affection contribute significantly to the variance after effects of social status and parental characteristics have been controlled, $R^2 = .261$, $F(27, 151) = 2.40$, $p = .0003$.

As predictors of personal crimes, the model accounts for 35.7% of the variance, $F(45, 151) = 1.87$, $p = .0028$. The three more direct measures of child rearing contribute significantly to the variance after effects of social status and parental characteristics have been removed, $R^2 = .244$, $F(27, 151) = 2.13$, $p = .0023$.

As predictors of the total number of serious crimes for which the men had been convicted, the model accounts for 39.1% of the variance, $F(45, 151) = 2.16$, $p = .0003$. Parental characteristics account for 5.9% of the variance after effects of social status have been controlled, $F(7, 151) = 2.45$, $p = .0209$. The child-rearing variables account for 26.0% of the variance, $F(27, 151) = 2.39$, $p = .0005$, after removing effects of both social status and parent characteristics.

Adding information about whether or not a man had been reared in a home marked by paternal absence did not reliably increase the accuracy of any of the predictions.[11]

Within the (relatively restricted) range of social class represented in the study, the contribution of social status to the variance in crimes was not statistically reliable. On the other hand, both parental characteristics and child-rearing practices were reliably related to the number of crimes for which the subjects had been convicted.[12]

Approximately a third of the 200 men coded on all six variables describing home atmosphere had been convicted for at least one serious crime. A discriminant function based on the variables describing home atmosphere for these 200 men correctly identified 147

[11] R^2 was increased by .002 for property crimes, .007 for personal crimes, and .001 for total crimes.

[12] Without controlling for social status, parental characteristics and child-rearing variables accounted for 36.7% of the variance in property crimes, $F(34, 162) = 2.76$, $p \leq .0001$, 30.8% of the variance in personal crimes, $F(34, 162) = 2.12$, $p = .0010$, and 36.3% of the variance in total number of serious crimes, $F(34, 162) = 2.71$, $p \leq .0001$.

Table 4
Results of Discriminant Function Analyses

Dependent and independent variables	Correct as criminals		Correct as noncriminals		Overall accuracy		% improvement over chance	$z > p$
	n	%	*n*	%	*n*	%		
All subjects								
Ever criminal								
Home atmosphere	71	67.6	129	76.7	200	73.5	19.3	.0001
Adult criminal								
Home atmosphere	48	56.3	152	87.5	200	80.0	16.5	.0001
Men living in Massachusetts through the age of 40								
Ever criminal								
Home atmosphere	60	81.7	92	70.7	152	75.0	22.8	.0001
Adult criminal								
Home atmosphere	42	71.4	110	84.6	152	80.9	20.9	.0001
Juvenile delinquency record	42	45.2	110	83.6	152	73.0	13.0	.0011

(73.5%) as criminals or noncriminals; random predictions based on prior probabilities would be expected to identify only 54.2% correctly,[13] $z = 5.48$, $p < .0001$. The function based on parental aggression, maternal self-confidence, paternal deviance, supervision, maternal affection, and parental conflict correctly identified 76.7% of the noncriminals and 67.6% of the criminals. (See Table 4.)

Forty-eight men had been convicted for serious crimes after their 18th birthdays. The six variables describing home atmosphere provided a discriminant function which correctly identified 27 (56.3%) of the 48 adult criminals and 133 (87.5%) of the 152 men without records for convictions as adults. Predictions based on the descriptions of home atmosphere provided a 16.5% improvement over the 63.5% expected from random predictions based on prior probabilities, $z = 4.85$, $p < .0001$. (See Table 4.)

After discarding men who had died before the age of 40, migrated from Massachusetts, or who had not yet been found, 152 men who were living in Massachusetts at least until the age of 40 and whose case records had been coded for all six variables describing home atmosphere remained for discriminant function analyses. Among these men, the discriminant function correctly identified 75.0%, a slight improvement over the rate of correct identification among the total group of men and a 22.8% improvement over random procedures based on prior probabilities, $z = 5.63$, $p < .0001$. (See Table 4.) This discriminant function correctly identified 81.7% of the 60 criminals and 70.7% of the 92 noncriminals.

A breakdown of the results shows that the discriminant function had correctly classified as criminal 78.1% of those convicted only for property crimes, 78.6% of those convicted only for personal crimes, and 92.9% of those

[13] The model used to estimate predictions based on chance assumes that the number of predictions as criminal would be proportional to the actual distribution of criminals among subjects. Alternative models that might be considered range from assuming that each individual is as likely to be convicted as not (which would result in an expectation for correct predictions among half the noncriminals and half the criminals) to assuming that all or no individuals would be convicted. Although a "rational bet" would maximize correct predictions by predicting that all individuals would fall into the larger class, this model is inappropriate when the interest is in correct identification of those in the smaller class. An equiprobability model for the discriminant function analysis based on family atmosphere resulted in correct sorting of 68% of the men (62% of the noncriminals and 79% of the criminals) in terms of whether or not they had been convicted for serious crimes.

convicted for both property and personal crimes.

Among the 60 men convicted for serious crimes and still living in Massachusetts at the age of 40, 18 (30.0%) had been convicted only as juveniles, 23 (38.7%) had first been convicted after the age of 18, and 19 (31.7%) had been convicted both as juvenile and as adults. Were one to predict that only and all juvenile delinquents would be convicted as adults, the prediction would be correct for 73.0%, an improvement over an expectation of 60.0% from random procedures based on prior probabilities, $z = 3.27$, $p = .0011$. This prediction would be correct for 45.2% of the adult criminals and for 83.6% of the men not convicted as adults. Predictions based on juvenile records would, of course, be right for *none* of the men first convicted as adults (54.8% of the adult criminals) and for only 51.4% of the juvenile delinquents.

Among men living in Massachusetts at the age of 40, the discriminant function analysis based on home atmosphere during childhood correctly identified 80.9% as criminal or noncriminal after the age of 18. (See Table 4.) Use of the variables describing home atmosphere during childhood resulted in a 20.9% improvement over chance identification, $z = 5.26$, $p < .0001$, and a 7.9% improvement over predictions based on the subjects' juvenile criminal histories, $z = 2.19$, $p = .0282$. This function correctly identified 71.4% of the adult criminals and 84.6% of the noncriminals. The discriminant function based on home atmosphere correctly identified as criminals 65.2% of the men who had first been convicted as adults. In terms of their subsequent criminal records, this discriminant function correctly sorted 78.4% of the juvenile delinquents and 81.7% of those who had not been juvenile delinquents.[14]

Summary and Discussion

Recent criticism of the assumption that child-rearing practices have an important impact on personality development posed the issue addressed in this research. In order to evaluate the assumption, records describing home atmosphere during childhood, recorded during childhood, were linked with records of subsequent criminality, gathered when the subjects were middle-aged. The two sources of information were independent: data collection had been separated by several decades, the data had been coded by different people, and the coders had no access to information other than that which they were coding. Therefore, measures of home atmosphere were uncontaminated by retrospective biases and measures of subsequent behavior were uncontaminated by knowledge of home background.

Records describing home atmosphere had been written between 1939 and 1945. These records were case reports of counselors' repeated home visits to the 201 boys included in this study. The case records were coded, in 1957, to provide descriptions of home atmosphere.

Information about criminal behavior was gathered from court records, 30 years after termination of the program from which descriptions of home atmosphere had been collected. Subjects were considered criminals if they had been convicted for serious crimes (those indexed by the Federal Bureau of Investigation).

In preliminary analyses, six of seven variables describing home atmosphere were reliably related to criminal behavior. Only father's absence failed to distinguish criminals from noncriminals. Considering the emphasis given to broken homes as a source of subsequent criminality (e.g., Bacon, Child, & Barry, 1963; Glueck & Glueck, 1951; Wadsworth, 1979; Willie, 1967), this finding is worthy of note.

Multiple regression analyses indicated that six variables describing home atmosphere in childhood account for a significant proportion of the variance in number of convictions for serious crimes. After controlling effects of differences in social status, parental characteristics and child-rearing variables ac-

[14] The "rational bet" that men not convicted as juveniles would not be convicted as adults would be correct for 80% of the men not convicted as juveniles. Since this bet would be correct only for the noncriminals, the prediction would fail to identify correctly any of the critical group: men first convicted as adults.

counted for 32.2% of the variance in number of convictions for property crimes and 30.3% of the variance in number of convictions for personal crimes. The three most direct measures of child rearing (supervision, mother's affection, and parental conflict) accounted for approximately a quarter of the variance in number of convictions for serious crimes—after effects of both social status and parental characteristics had been removed.

Discriminant function analyses based on the six variables describing home atmosphere correctly identified 73.5% of the men as either subsequently criminal or noncriminal; further, these six variables provided a function that for 80% of the men correctly discriminated between those convicted and those not convicted for serious crimes as adults.

As compared with analyses for the total sample, the discriminant function analyses were (slightly) more accurate when used to predict behavior among the men whose criminal records provided the most complete histories of convictions. Among men living in Massachusetts at least to the age of 40, these functions correctly identified 75% as ever criminal or as noncriminal and 80.9% as criminal or noncriminal after the age of 18. Limiting analyses to men living in Massachusetts controlled any differences contributing to migration or early death; therefore, the accuracy of discriminant functions among this subsample is interpreted as supporting the view that home atmosphere during childhood contributes to criminality.

When used to identify men convicted as adults, the discriminant function identified as criminals almost two-thirds of the men first convicted after the age of 18. This function also correctly sorted more than three-quarters of the juvenile delinquents, distinguishing between those who were and those who were not adult criminals.

Although the discriminant functions based on home atmosphere were surprisingly successful in identifying men who were to become criminals, it would be a mistake to conclude that the longitudinal design of this research has led to recognition of the causes of crime. This research is limited not only by its subjects (all of whom were reared in congested urban areas during the thirties and early forties) but also by the hypotheses considered. In this research, parental aggression, paternal deviance, maternal self-confidence, supervision, mother's affection, and parental conflict indexed home atmosphere; unconsidered variables might better describe the features in the child's home that affect his behavior. In this research, the possibly confounding variable of social status was considered; other conditions might account for the apparent link between home atmosphere and crime. Nevertheless, the evidence from this study suggests that parental behavior does have an important impact on subsequent behavior: predictions of adult criminality based on knowledge of home atmosphere were not only markedly more accurate than chance—they were also more accurate than predictions based on the individuals' juvenile criminal records.

Instructions for Submission of Manuscripts

Papers submitted to the *Journal of Personality and Social Psychology* after April 1, 1979 will be considered under new policies approved by the Publications and Communications Board. Effective with the 1980 volume of the journal, the following policies will apply:

The *Journal of Personality and Social Psychology* publishes original papers in all areas of personality and social psychology. It emphasizes empirical reports but may include specialized theoretical, methodological, and review papers. Beginning in April 1980, the journal will be divided into 3 independently edited sections: ATTITUDES AND SOCIAL COGNITION, INTERPERSONAL RELATIONS AND GROUP PROCESSES, and PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES. Authors should submit manuscripts to the appropriate section editor according to the section definitions and manuscript preparation instructions provided on page 468 of the March 1979 issue of the journal.

Section editors' addresses are as follows: ATTITUDES AND SOCIAL COGNITION, Melvin Manis, Editor, Research Center for Group Dynamics, Institute for Social Research, University of Michigan, Ann Arbor, Michigan 48106; INTERPERSONAL RELATIONS AND GROUP PROCESSES, Ivan D. Steiner, Editor, Department of Psychology, University of Massachusetts, Amherst, Massachusetts 01003; PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES, Robert Hogan, Editor, Johns Hopkins University, Department of Psychology, 33rd and Charles Streets, Baltimore, Maryland 21218.

Are Causal Attributions Causal? A Path Analysis of the Cognitive Model of Achievement Motivation

Martin V. Covington and Carol L. Omelich
University of California, Berkeley

The causal assumptions of Weiner's cognitive reinterpretation of the traditional theory of achievement motivation are tested. This research asks the question, "Do achievement motivation groups differ in their affective reactions, expectancy of future success, and subsequent test performance as a consequence of attributions made for a previous test outcome?" Subjects ($N = 206$) were college students varying in resultant achievement motivation who experienced feelings of failure in a course test and chose to take the exam a second time under a mastery learning system. After feedback on first test performance, students made attributions for their initial failure, indicated degree of shame, and rated their expectancy for success on the second test opportunity. Treatment of this system of nonmanipulated variables by path analysis techniques provides little support for the contention that variations in expectancy and retest performance depend on attributions made for a previous failure. Affect depends in part on internal attributions, but in a direction opposite to predictions. An alternative interpretation of the role of cognitive attributions in the achievement process is explored.

The most widely known theory of achievement motivation (Atkinson, 1957, 1964) holds that achievement behavior is the result of an emotional conflict between hope of success and fear of failure. Recently Weiner and his colleagues (Weiner, 1972, 1974, 1977; Weiner, Frieze, Kukla, Reed, Rest, & Rosenbaum, 1971) have suggested a cognitive reinterpretation of this traditional theory. It is proposed that need for achievement (nAch) is mediated by perceptions of causality that in turn influence affective reactions to success and failure, expectancy of future success, and subsequent performance. Thus achievement motivation, originally conceived solely in terms of differential emotional anticipations, becomes heavily imbued with cognitive elements. In this new schema nAch is assigned a subordinate status as one of many antecedents to achievement, with cognitive attributions becoming the major causal determinants of achievement behavior.

Following Heider (1958), Weiner proposes ability, effort, luck, and task difficulty as among the major perceived causes of achievement performance (Weiner, 1972, 1977, 1979). There is general consensus that high and low nAch individuals harbor differential explanations about the causes of their successes and failures (Weiner et al., 1971; Weiner, Heckhausen, Meyer, & Cook, 1972; Weiner & Kukla, 1970; Weiner & Potepan, 1970), and it is precisely these differences that are taken as the essence of individual differences in achievement motivation. Generally speaking, persons motivated to approach success (high nAch) attribute failure to lack of effort and success to their ability, whereas failure-avoiding (low nAch) persons tend to ascribe failure to lack of ability and success to external factors such as luck. The

The authors wish to thank Richard S. Lazarus, Joy Stapp, Alan Zonderman, the action editor, and anonymous reviewers for their helpful comments and suggestions on an earlier draft of this article.

cognitive model specifies several sequential steps in the achievement process resembling an information-processing system.

1. First, following a given achievement outcome, success or failure is interpreted retrospectively in terms of the four major attributional elements and according to the predisposing individual differences in nAch.

2. Second, these differential perceptions of causality, in turn, mediate affective reactions to performance—shame in failure and pride in success—as well as the individual's expectations about the probability of future success. For example, in failure, self-ascriptions to low effort—characteristic of high nAch individuals—intensify shame and act to maintain an expectation for future success. By contrast, low ability ascriptions lead to less shame but lowered future expectations, a pattern typical of low nAch persons.

3. As a final step, achievement performance is determined by causal ascriptions acting indirectly through both pathways of affective reaction and expectations of future success. In effect, high nAch persons who have reacted to failure with chagrin yet have maintained an undiminished optimism for the future (due to their attributional biases) are likely to perform far better on the next occasion than are low nAch individuals. The entire process from Step 1 through Step 3 is repeated from one performance to the next.

This ingenious cognitive analysis has stimulated a large volume of research (for reviews see Weiner, 1972, 1974, 1977). Yet despite the impressive numbers, several shortcomings limit the theoretical utility of the cognitive viewpoint. First, with but rare exception (e.g., Weiner & Potepan, 1970), research has been carried out in the laboratory rather than in naturally occurring settings. Second, investigators have typically confined themselves to an examination of one link in the model at a time, to the exclusion of other antecedent and subsequent relationships. While a few studies have incorporated additional variables (e.g., Meyer, 1970 [fully described in Weiner et al., 1972]; Weiner & Sierad, 1975), none have yet evaluated the entire model as a dynamic system in a real-life setting. As a result, the central assumption of the primary causal role of attributions lacks sufficient empirical support to warrant its unqualified acceptance. Thus we ask: "Do achievement motive groups differ in affective reactions, expectancy of future success and subsequent performance *as a consequence* of attributions made for a previous test outcome?" At stake here is the basic assumption that attributions are in themselves a sufficient explanation for achievement behavior. According to the model, once nAch acts to trigger differential attributional biases in response to success or failure feedback (Step 1), it plays no further role as a major, direct determinant of the more distal psychological events that influence retest performance (i.e., expectancy and affect). Whether or not we are justified in deleting the concept of need achievement from theories of achievement behavior has yet to be empirically demonstrated.

The purpose of the present study is to trace the sequential cause and effect network of relationships assumed by the cognitive model in order (a) to explore both the separate and overlapping causal roles played by nAch and cognitive attributions in determining variations in achievement behaviors and (b) to determine whether or not the proposed attributional mediators act in accord with theoretical predictions. To this end we have gathered data on all the crucial elements specified by the model in an achievement context of test-taking in the classroom and in the chronological order that conforms to the theory. This analysis is confined to subjects who experienced subjective failure in the first of two test-taking opportunities.

The primary method for analyzing this system of nonmanipulated variables is path analysis (Anderson & Evans, 1974; Duncan, 1966, 1975; Heise, 1975; Kerlinger & Pedhazur, 1973; Werts & Linn, 1970). Path analysis allows for all determining factors as specified by a causal model to be incorporated into an overall predictive analysis, thereby permitting an estimation of the relative contribution (both direct and indirect) of each determinant to variations in the dependent variable(s). In this case, the dependent variables of interest are various facets of achievement behavior.

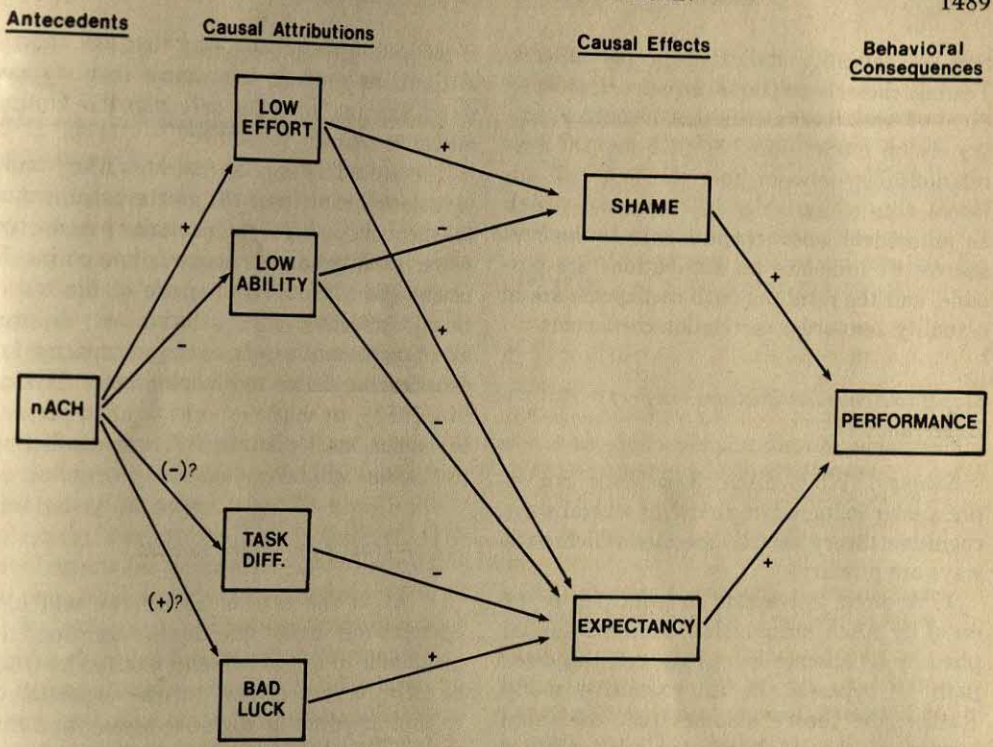

Figure 1. Causal pathways of influence postulated by the cognitive model of achievement motivation in the task reevaluation stage following failure.

For a proper interpretation of the analyses to follow, it is important to bear in mind that path analysis is not a procedure for demonstrating causality. Rather it is a method for tracing out the implications of a set of causal assumptions that the theoretician is willing to impose on a system of relationships. In essence, we attempt to answer the question "Does the cognitive model fit the data adequately?" by comparing the *observed* relationships among the variables with the *expected* relationships. Since the presumed relationships and directionality among the elements of the cognitive model have been so well specified, the application of recursive path analytic techniques does not allow for the testing of an alternate model. For instance, nAch is seen as an antecedent that predisposes individuals to particular attributional patterns. This causal ordering precludes the testing within the path analysis system of any alternate hypothesis that concerns the effect of attributions on nAch.

It will prove helpful to indicate in advance the kinds of hypotheses and specific causal assumptions we will examine, the order of the data presentation, and how path-analytic techniques will be employed. This presentation will be aided by reference to Figure 1, which schematizes the cognitive events described earlier. The unidirectional arrows and accompanying algebraic signs indicate the main pathways of causal influence to be tested.

Step 1: nAch→Attributions

Cognitive theory predicts a positive relationship between effort ascriptions and nAch in failure, that is, as nAch level increases, so do ascriptions to low effort. Similarly, we expect a negative relationship between nAch and ability ascriptions such that as nAch level increases, attributions to low ability decrease. The nAch pathways to luck and task ascriptions carry question marks, since the model makes no specific predictions regarding motive group predispositions. However, the stable (task) and unstable (luck) qualities of these two external elements suggest the direc-

tion of causality indicated in parentheses. Testing these predictions involves regressing each of the four attributional sources separately on nAch. Since the first step involves relationships between only the first two adjacent sets of variables in the model (nAch as antecedent and attributions), no *indirect* sources of influence on attributions are possible, and the resulting path coefficients are in actuality zero-order correlation coefficients.

Step 2: nAch→Attributions→Affect/Expectancy

Shame. While nAch dispositions can express their influence on shame in several ways, cognitive theory clearly specifies which pathways are primary.

1. A direct effect can, in principle, be exerted by nAch membership. However, as implied by its absence from Figure 1, this direct path is bypassed in the cognitive model. Rather, the theory assumes that the causal burden of the nAch→shame relationship is transmitted *indirectly* via attributions, with nAch serving as no more than an instigator of attributional biases. Path analysis allows for a comparison of the relative importance of these two nAch pathways.

2. The cognitive position also assumes that shame is influenced *directly* along an internal–external dimension of causal ascriptions, with internal factors being the more important determinants. While this dimensional distinction has been deemphasized in recent treatments and additional affective reactions identified (Weiner, 1979; Weiner, Russell, & Lerman, 1978, Note 1), it is still assumed that shame is a consequence of ability and effort attributions. Thus shame is said to be maximized when failure is perceived as occurring through lack of effort, especially among highly able individuals, and minimized when the individual, particularly if he is of low ability, has tried hard. This leads to the prediction of a positive relationship between effort ascriptions and shame, that is, as attributions to low effort increase, so does shame. Correspondingly, we expect a negative relationship between ability ascriptions and shame such that as low ability attributions increase shame is reduced. This is not to say that low ability attributions produce less shame than do external explanations, but only that low ability mitigates shame.

The preceding implies that high nAch individuals will experience the greatest shame due to their disposition to maintain a sense of power (ability) and to blame failure on insufficient effort. However, because of the traditional, affective interpretation of failure-avoiding persons as possessing a "capacity for experiencing shame and humilitation" (Atkinson, 1957), we might expect low nAch persons to be the most distressed. These conflicting predictions will be evaluated.

Expectancy for future success.

1. As in the case of shame, we will also address the basic question concerning the magnitude of causal influence exerted by nAch directly on expectancy (nAch→expectancy) as contrasted to the cognitive assumption that the only notable pathways of significance come indirectly from nAch mediated through attributions.

2. Expectancy is predicted to vary directly along the stable/unstable attributional axis. Specifically, expectancy is said to be higher when failure is attributed to unstable elements (effort, luck) and lower when ascribed to stable ones (ability, task). Accordingly, we ought to find significant, positive path coefficients between expectancy and ascriptions to low effort and bad luck; and conversely, negative path coefficients between expectancy and attributions to low ability and high task difficulty.

It follows from the foregoing that high nAch persons will maintain greater expectations for future success after failure than will low nAch persons, owing to the tendency of the former group to attribute failure to unstable elements, especially lack of effort. While several studies confirm that low nAch persons harbor lower expectations for success (Atkinson, Bastian, Earl, & Litwin, 1960; Kukla, 1972a, 1972b; Moulton, 1974) there is little evidence that this condition is influenced by attributional mediators. Path analysis allows us to evaluate the relative im-

portance of this presumed indirect causal pathway.

Step 3: nAch→Attributions→Affect/Expectancy→Retest

Cognitive theory holds that attributions influence performance largely through their determination of expectancy and affect.

1. To clarify the causal role of nAch, we will assess the degree to which nAch exerts a direct impact on performance in contrast to its indirect influence through cognitive mediators.

2. The assumption that affect and expectancy influence performance largely because of antecedent variations in attributions leads us to expect a relatively large indirect effect of attributions on performance as compared to the magnitude of the direct influence exerted by expectancy and shame. Correspondingly, the direct influence of attributions on performance should be negligible. This latter prediction takes on some importance in light of recent work suggesting direct attributional influence (e.g., Dweck, 1977; Latta, 1976).

As we move through the various steps of the cognitive model, the number of indirect paths of potential influence increases progressively. In principle, nAch can express its influence on performance indirectly through some 14 different indirect pathways. Although most of these paths contribute only negligibly to variations in performance, and few of the paths are of more than passing interest, we must nonetheless deal with the unwanted complexity that results. Consequently, at each of the three major steps in our analysis we will also employ a stepwise regression technique that allows for an incremental F test as a summary statistic. While not path-analytic in interpretation, it provides a valuable adjunct perspective indicating whether or not the addition of each successive predictor variable (or set of variables) increases significantly the total explained variance in the particular dependent variable under consideration.

Method

Subjects and Procedure

Subjects were drawn from among 439 students enrolled in an introductory psychology course that featured a modified mastery structure (Block, 1977, Note 2). At the end of each instructional unit two equivalent multiple-choice tests were administered two days apart. If students wished the chance to improve, they had the option of taking the second test after further study. Two hundred and six students (100 females; 106 males) who considered their first performance unsuccessful and chose to take the second test served as subjects. The present data were collected at the end of the second instructional unit.

Measures

Both tests were scored, and the results were known to students before they left the examination room. After receiving grade-equivalent feedback on the first test, students completed a brief questionnaire.

Causal ascriptions for failure. Students indicated the causal importance of each of Weiner's attributional sources using a format adapted from Feather (1969):

To what extent do you consider that your unsuccessful performance was due to each of the following factors?

The examination was difficult.
I did not study very much.
I had back luck (e.g., test stressed different materials).
I lack the skill and ability.

Each attribution was rated separately on a 7-point Likert-type scale from 1 (not a cause) to 7 (very much a cause).

Affective reactions. Students also estimated degree of shame as a result of their unsatisfactory performances. Again, ratings were made on a 7-point scale from 1 (not at all) to 7 (very much).

Grade expectancy. Students indicated the grade that they expected to get on retesting. Letter grades were converted to standard grade-point equivalents. While some researchers stress measurement of expectancy change (McMahan, 1973; Valle & Frieze, 1976), our use of subsequent expectancy level follows the practice of the majority of investigators (e.g., Weiner, Nierenberg, & Goldstein, 1976).

Retest performance. Number correct on the second test served as the performance measure.

Resultant achievement motivation. Following the procedures of Weiner and Potepan (1970), an index of resultant achievement motivation was derived for each subject by taking the difference between z-score transformations on the Mehrabian Achievement Risk Preference Scale (MARPS) (Mehrabian, 1968, 1969) and the debilitating anxiety subscale of the Achievement Anxiety Test (AAT) (Alpert & Haber, 1960). These two indices were administered during preenrollment for the course, thereby occuring in the antecedent position dictated by the model. Selection of the present failure sample did not result in a biased subset of the nAch distribution. The mean nAch of these subjects ($M = -.081$) does not differ from that of the entire class ($M = .068$), $t(560) = 1.21$, $p < .20$. Moreover, the resultant scores of failure

subjects classified as high ($M = 1.08$) and low ($M = -1.14$) on a median split do not differ from those in the class at large ($M_H = 1.21$, $p < .20$; $M_L = -1.07$, $p < .30$), indicating equivalent heterogeneity.

Results and Discussion

The means, standard deviations, and intercorrelations among the variables of the cognitive model are presented in Table 1. The cognitive model assumes no causal reciprocity between same-level variables (i.e., among attributions or between expectancy and shame). In path-analytic terms, any observed residual covariation (e.g., −.23 between task and effort ascriptions) need not be zero, but may be assumed to originate from a common dependency on nAch or on variables outside the model. Thus these same-level covariations do not influence the causal structure and are therefore not dealt with further.

Figure 2 presents the results of the total path analysis. The values associated with the unidirectional arrows are path (standardized regression) coefficients (P). Epsilon [$E = (1 - R^2)^{\frac{1}{2}}$] represents the path coefficient value of all sources of variation not specified by the model. Preliminary path analyses by sex produced virtually identical results, hence male and female data are combined in this present analysis. These null results are interesting in light of previous evidence of sex differences in achievement attributions and their consequences (e.g., Dweck, 1977; Feather, 1968, 1969; House & Perney, 1974; Nicholls, 1975). The present findings probably point to the relatively modest role played by sex when all aspects of the model are allowed to vary naturally.

Step 1: nAch→Attributions

Path coefficient values derived from regressing each of the four attribution elements singly on nAch are presented in the left-hand portion of Figure 2. The results indicate that variations in ability and luck ascriptions have a significant dependency on nAch ($P = -.341$ and $-.237$, $p < .05$, respectively), but that effort ($P = .048$) and task ascriptions ($P = -.066$) do not. Consistent with previous results (Kukla, 1972a; Weiner et al., 1971, 1972; Weiner & Potepan, 1970), failure experiences are found to elicit greater ascriptions to low ability among low nAch persons. However, the finding that low nAch persons ascribe their failures to bad luck was unexpected and may have been precipitated by the highly ego-involving nature of the present task. Those students who expect to fail may be acting defensively to disavow personal

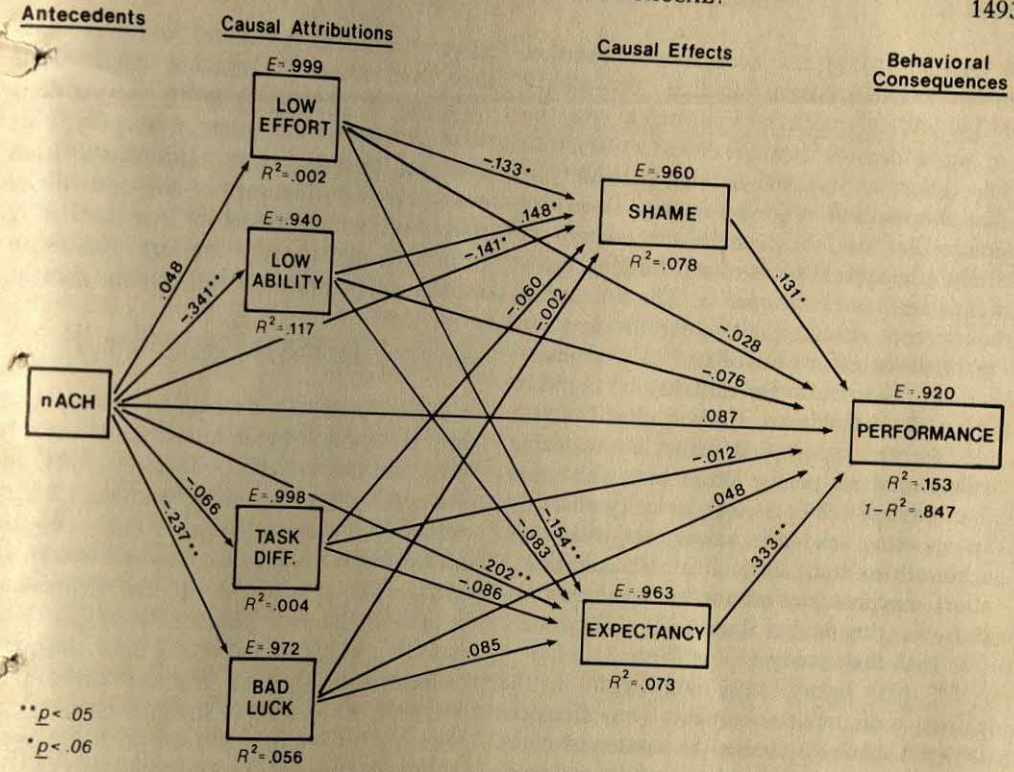

Figure 2. Path diagram of effects of nAch, causal attributions, expectancy, and shame on subsequent performance following failure.

responsibility (Covington & Omelich, Note 3). Whatever the explanation, inspection of Figure 2 indicates that luck as a causal attribution exerts no further influence on any of the distal components of the model. Similarly, task difficulty also drops out as a causal factor, having established neither a dependency on nAch nor a clear causal influence forward in the presumed chain of psychological events. Yet we cannot conclude that perceptions of task difficulty exert no influence on achievement behavior; we know they do. Variations in task complexity have been shown to influence expectations for future success (Atkinson & Feather, 1966) as well as reactions to a given performance (Parsons & Ruble, 1972) and to moderate performance (Marso, 1969; Woodson, Note 4). The fact that the task demands (test) were identical for all students probably led to a restricted range of task attributions, causing an underestimation of the true causal role of task variables.

The prediction that high nAch persons differently ascribe failure to insufficient effort was not upheld by the present data ($P = .048$, $p < .50$). Other attempts to substantiate this hypothesis have also met with disappointment (e.g., Weiner et al., 1971; Weiner & Kukla, 1970; Weiner & Potepan, 1970). Several explanations for this general failure to confirm the hypothesis appear tenable. First, according to the proposed distinction between stable and temporary effort (Rest, Nierenberg, Weiner, & Heckhausen, 1973; Weiner, 1974) cognitive predictions should be upheld if students are responding predominantly to low effort as a temporary state of affairs. But to the extent that some subjects, notably low nAch individuals, are reflecting a more trait-like disposition never to try (perhaps from a resignation born of a history of past failures), the predicted nAch→effort attribution linkage will be canceled out. Second, a self-serving, defensive interpretation is also viable. Inferences to low ability evoke shame (Covington

& Omelich, 1979), and because a combination of high effort/failure signifies low ability (Kun & Weiner, 1973), some students may be acting to deceive themselves and others with false effort ascriptions. A third possibility is that the real difference between nAch motive groups lies not so much in the *amount* of study (the typical focus of attributional questionnaires) as in its *quality*. The number of hours spent studying, either for the first test or for the retest, was unrelated to nAch membership. The reason for this may be found in the work of Goldman, Hudson, and Daharsh (1973), who report that many low-achieving college students persist longer in their studies than do high achievers, a superiority offset by an opposing tendency among yet other low achievers to study little if at all. Additional effort may not pay off for low achievers because nagging doubts about their ability interfere with their study (Wine, Note 5).

All three lines of speculation point to the existence of important qualitative differences between nAch groups in the matter of effort expenditure that have yet to be fully explored. Meantime, the predicted nAch→effort attribution relationship remains unconvincing. To the extent that nAch groups may differ in affective reactions to failure, future expectations, and retest performance itself, these variations do not appear to depend on their postdictive effort ascriptions. Naturally, this does not preclude effort attributions from exerting a direct influence on the more distal components of the model or from indirectly influencing performance through shame or expectancy, pathways we will examine shortly.

Step 2(a): nAch→Attributions→Affect

Table 2 presents the results of decomposing the relationship between nAch and shame into direct and indirect effects. Indirect effects indicate the degree to which a change in an independent variable (nAch) influences an intervening variable (cognition), which in turn results in variations in the dependent variable of interest (shame). They are estimated by summing the products of the path coefficients of the one or more paths that intervene. At present no significance tests are available for indirect effects except by evaluating the overall goodness of fit to the model.

Inspection of the first column in Table 2 indicates a significant zero-order correlation

Table 2
Decomposition of Zero-Order Correlations of Achievement Motivation With Shame, Expectancy, and Performance

Relationship	Shame	Expectancy	Performance	
Zero-order correlation	−.194*	.209*	.145*	
Direct effect (P)[a]	−.141	.202*	.087	
Total indirect effect	−.053	.007	.058	
Effort (E)	−.007	−.002	−.002	.014
Ability (A)	−.051	.026	.027

[a] Standardized regression coefficients.
* $p < .05$.

between nAch and shame of −.194 ($p < .05$) that decomposes into a direct effect from nAch of −.141 ($p = .054$), which falls just short of the conventional standard of significance, and into a total indirect influence on shame from nAch mediated through attributions of −.053. Reading down the remainder of column 1, we note that only ability emerges as a substantial transmitter of nAch influence (−.051), accounting for virtually all the total indirect influence on shame. The contribution of effort is negligible (−.007). Other attempts to substantiate attributions as mediators of affect among nAch groups have fared little better. While Meyer (1970) demonstrated that high and low nAch subjects differed in ability ascriptions following failure, no relationship was found between this differential ascriptive pattern and degree of affective reaction to failure. Similarly, Weiner and Potepan (1970) found nAch membership predictive of anxiety over an upcoming school test, but again affect was unrelated to accompanying attributions.

These data provide little support for the view that the principal influence of nAch on shame is mediated indirectly via cognitive mechanisms. Contrary to what would be expected if nAch acted only to initiate differential ascriptions, there is a tendency for nAch to exert a direct influence on shame in its own right, an effect certainly greater than that transmitted through attributions.

Now consider the direct influence of attributions on shame, irrespective of nAch. Figure 2 indicates two noteworthy direct pathways: one from effort ascriptions to shame ($P = -.133$, $p < .06$) and the other between ability ascriptions and shame ($P = .148$, $p < .06$). While this pattern of findings is consistent with Weiner's original contention that shame is determined primarily by variations in the internal elements of effort and ability, the direction of these influences is opposite to that predicted. First, ascriptions to low effort tend to decrease rather than increase shame; and second, ascriptions to low ability act to increase, not reduce, shame. These trends are consistent with recent findings (Covington & Omelich, 1979, in press; Nicholls, 1975, 1976; Sohn, 1977; Covington, Spratt, & Omelich, Note 6) indicating that students take pride in high self-ability attributions and experience shame at low ability, a dynamic intensified in repeated failure (Covington & Omelich, Note 7).

One consequence of this ability valuing is that high nAch subjects tend to experience less shame than do low nAch subjects, not only because of the maintenance of high ability ascriptions despite failure but also as a direct function of their motive group membership. This finding favors the traditional interpretation of failure-avoiding persons as "possessing a capacity for experiencing shame" (Atkinson, 1957) and lends weight to Nicholl's conclusion (1976) that the key difference between high and low resultant achievement motivation students lies in their differential self-concepts of ability.

Originally Weiner assumed that students would internalize teacher reinforcement patterns that favor achievement through effort and would view low ability as a mitigating circumstance in failure. However, in light of subsequent evidence (cited above), Weiner has recently acknowledged (Weiner et al., 1978) that ability and effort attributions can magnify affective reactions, depending on whether the individual is a teacher or student. The present data underscore the importance of maintaining a distinction between rewards and punishment from others and personal reactions to performance outcomes.

The left-hand portion of Table 3 displays the results of incremental F tests providing an overall summary of the path analysis for shame. As the first predictor variable entered, nAch accounts for 48.5% (.038) of the explained variation in shame through all paths of influence, direct and indirect, $F(1, 200) = 8.16$, $p < .01$. Next, the four attributional sources combined add .040 to R^2 and account for the remaining 51.5% of the explained variance ($R^2 = .078$), $F(4, 200) = 2.16$, $p < .08$. Only the internal elements of ability, $F(1, 200) = 3.81$, and effort, $F(1, 200) = 4.13$, contribute significantly to this total ($p < .05$), with the contribution of effort coming entirely from its direct influence on shame. However, it is reasonable to wonder if the introduction of nAch as the first variable in

Table 3
Incremental F Tests: Effects of Achievement Motivation and Attributions on Shame and Expectancy

Antecedent variable	*df*	Shame				Expectancy			
		R^2	Increment to R^2	F	% of R^2	R^2	Increment to R^2	F	% of R^2

Note. df residual = 200.
* $p < .05$.

our path analysis acted to attenuate the impact of attributions on shame, given the considerable variance shared by nAch and some of the attributional elements (see Table 1). Accordingly, an analysis with nAch deleted yields a significant effect of attributions on shame, $F(4, 201) = 3.22$, $p < .05$. While the internal attributions of ability ($p < .01$) and effort ($p < .07$) now account for virtually all the explained variance in shame (74% and 26%, respectively), there is a decrease in R^2 from .078 (with nAch included) to .060. However, this decrement fails to reach significance at the conventional level, $F(1, 200) = 3.68$, $p < .06$.

These results establish the importance of the direct influence of internal attributions on shame, even though their role as transmitters of motive dispositions is less than expected and in a direction opposite that predicted by the cognitive model. It could be argued that these data support the contention that nAch is "nothing more than one manifestation of differential attributions" (Weiner, Note 8), especially since deletion of nAch results in a nonsignificant decrement in explained variance. However, the present nAch data pattern, in conjunction with previously cited findings (Meyer, 1970; Weiner & Potepan, 1970), suggests that nAch does make a separate contribution to shame, independent of the predictive power it shares with ability attributions. Indeed, one further analysis deleting the four attributions from the prediction equation indicates a significant contribution from nAch, in the absence of any intervening influence of causal cognitions ($R^2 = .038$), $F(1, 204) = 7.98$, $p < .05$. Despite their commonality, we conclude that both motive dispositions and internal cognitive ascriptions exercise a direct and independent influence on shame.

Step 2(b): nAch→Attributions→Expectancy

The second column of Table 2 indicates a significant zero-order correlation between nAch and expectancy for future success of .209 ($p < .05$) that decomposes into a significant direct effect of .202 ($p < .05$) and a negligible indirect effect from nAch mediated through all four attributional sources of .007. We conclude that variations in expectancy have a substantial direct dependency on motive group membership and that contrary to cognitive predictions, attributions do not act as mediators for this covariation. The weight of previous evidence on failure does little to alter this conclusion. While Meyer (1970) reported that high and low nAch groups differed in their attributions to stable elements, these ascriptions led to expectancy shifts only among low nAch students. Moreover, Weiner

and Kukla (1970) found that although high nAch subjects reported greater ability levels, they did not as a consequence hold higher expectancies for future success. Thus it appears that whatever differential attributions high and low nAch persons make in response to failure, they play little part in determining expectancies for future success.

Now consider the evidence for a direct influence of attributions on future expectancy, irrespective of nAch membership. Whenever the direct attribution→expectancy linkage has been the sole focus of research, the evidence has overwhelmingly favored cognitive predictions (Fontaine, 1974; McMahan, 1973; Meyer, 1970; Rosenbaum, 1972; Valle, 1974; Weiner et al., 1976; the work of Rosenbaum, 1972, and Valle, 1974, is fully described in Weiner et al., 1976). These studies clearly demonstrate that expectations of future success remain higher when previous failures are attributed to unstable elements than to stable ones. In view of such agreement the present findings may appear puzzling. Figure 2 indicates that three of the four attributional elements (ability, luck, and task difficulty) exert no significant direct causal influence on variations in expectancy. This is also contrary to recently developed theoretical alternatives centering on learned helplessness (Abramson, Seligman, & Teasdale, 1978; Dweck, 1975, 1977; Covington & Omelich, Note 7), suggesting that self-ascriptions to low ability should produce expectancy decrements. However, it must be recalled that path analysis assesses the relative influence of each of many factors on a single dependent variable simultaneously. The role of attributions as direct causal mediators is probably overshadowed by the influential presence of nAch in the full model. When nAch is excluded from the path analysis and attributional sources are considered in isolation, the causal link between ability ascriptions and expectancy now approaches significance ($P = -.143$, $p < .06$), suggesting that this stable element acts to depress future expectancies of success. The insignificant role played by task ascriptions remains unchanged by these manipulations ($P = -.084$). This may reflect the possibility that, although it is a stable element, failure ascribed to a difficult task does not necessarily imply personal inadequacy and hence holds no particular implication for the future (Klein, Fencil-Morse, & Seligman, 1976; Tennen & Eller, 1977). Thus our data lend partial support to the hypothesized role of stable elements as mediators of future expectancy, while pointing up their relatively modest causal role when compared to other variables in the model.

We note in Figure 2 a significant direct, causal path from effort ascriptions to expectancy ($P = -.154$, $p < .05$), but in a direction opposite to that predicted. Rather than raising hopes for future success, low effort ascriptions for a previous failure appear to dash them. Although having studied little for a first test may in principle sustain optimism about future test outcomes, this is likely only if time permits sufficient additional study before the next test. When the time interval between tests is relatively short, as in the present study, students who did not prepare adequately the first time are probably less sanguine about a second chance. Weiner's notion of stable effort may also apply (Rest et al., 1973; Weiner, 1974, 1979). Consistent inaction in situations that clearly demand concentrated effort suggests an attitude of demoralization that carries with it negative expectations for future success. For some students a combination of low effort and pessimism for the future may simply reflect an underlying negative attitude regarding their sense of personal causality (deCharms, 1968, 1972). At the same time, these postdictive effort ascriptions may be partly defensive. The more effort expended in a failing cause, the more individuals are likely to underestimate actual time spent studying (Covington & Beery, 1976), a self-serving tactic that acts to confound cognitive predications.

The right-hand portion of Table 3 provides a summary of the findings for expectancy. An incremental F test indicates that nAch accounts for some 60% of the explained variance, $F(1, 200) = 9.38$, $p < .05$. Of all the attributional elements taken singly, only low effort contributes to any degree (although not significantly), accounting for half the remaining 40% of the explained variance in ex-

pectancy, $F(1, 200) = 3.28$, $p < .08$. Again to avoid underestimating the role of attributions as causal agents because of the significant covariation between nAch and attributions, the analyses in Table 3 were recalculated with nAch deleted. A significant decrease in R^2 is the result, from .072 (with nAch included) to .037, $F(1, 200) = 7.54$, $p < .01$. Thus nAch exerts a substantial influence on expectancy in the absence of any discernible impact of cognitions.

Step 3: nAch→Attributions→Affect/Expectancy→Retest

Inspection of column 3 in Table 2 reveals a significant zero-order correlation between nAch and retest performance of .145 ($p < .05$) that decomposes into a direct effect on performance of .087 and into a total indirect effect of .058. Five pathways make up the total indirect influence of nAch on performance. Three involve attributions as mediating links and should therefore make substantial contributions. The two remaining pathways involve only expectancy and affect, respectively, as the sole mediating links between nAch and performance and should in theory contribute relatively little to the total indirect effect. To simplify, we have squared and summed the individual contributions of each of these five pathways to permit a percentage interpretation.

1. *nAch→attributions→performance.* The value (.014) associated with the four bracketed entries in column 3 of Table 2 indicates the degree of nAch influence on performance mediated through variations in the four attributional sources combined. The absolute value of this effect (disregarding algebraic signs) represents roughly 15% of the total indirect effect of motive group on performance. Ability is the only attributional mediator of importance, accounting for most of the 15% contribution (13%). Previous research on this nAch→attribution→performance link has been inconclusive. Weiner and Sierad (1975) and Meyer (1970) report the relationship holding only for low nAch subjects, whereas Kukla (1972a) found it only among high nAch subjects. In light of the present data this inconsistency may be interpreted as due to the modest contribution of the nAch→attribution linkage to performance.

2. *nAch→attributions→shame→performance.* The internal dimensions of ability and effort have a negligible influence (−.008) on nAch group performance as mediated through shame. As expected, external elements play no part in this dynamic (.001). These combined sources account for only 1% of the total indirect effect.

3. *nAch→attributions→expectancy→performance.* Similarly, ascriptions to stable elements (.011) and to unstable elements (−.008) contribute little to the performance outcomes of nAch groups as mediated through expectancy. These combined sources account for 3% of the total indirect effect of nAch influence on performance.

4. *nAch→shame→performance.* Variations in shame produce a stronger indirect pathway of nAch influence on performance (−.018), accounting for 6% of the total indirect effect.

5. *nAch→expectancy→performance.* The most powerful source of indirect influences for nAch membership on performance is expressed through variations in expectancy (.066), accounting for 75% of the total indirect causal impact of motive group membership on performance.

In summary, the central proposition of cognitive theory, that performance outcomes among motive groups depend largely on differential attributions made for previous failures, finds little support. The main mediators of differential performance prove to be expectancy and, to a lesser degree, ability and shame, which together account for some 94% of the total indirect effect of motive group membership on performance.

Next, consider the direct effect of expectancy, shame, and the four elements of causal ascription on performance. Figure 2 indicates that the single most powerful source of direct influence is expectancy ($P = .333$, $p < .05$), followed by shame, which makes a modest, although nonsignificant, contribution ($P = .131$, $p < .06$). The direct path coefficient for each attribution is also nonsignificant (effort, $P = -.028$; ability, $P = -.076$; task difficulty, $P = -.012$; and luck, $P = .048$).

Table 4
Incremental F *Tests: Effects of Achievement Motivation, Attributions, Expectancy, and Shame on Performance*

* $p < .05$.

These four path coefficients were recalculated excluding nAch. However, the new values differ little (−.027; −.098; −.012; and .036, respectively), and in no cases were changes sufficient to achieve statistical significance. Traditionally, theoretical interest has focused on the indirect mediating role of attributions, although the weight of evidence (Dweck, 1975, 1977; Kukla, 1972a; Weiner et al., 1972; Weiner & Potepan, 1970; Weiner & Sierad, 1975) suggests the existence of direct attributional links to performance, at least in the case of failure. However, the present findings cause us to wonder about the importance of such linkages relative to other direct and indirect pathways in the model.

As the last step, we assess the indirect influence of attributions mediated through expectancy and shame (attributions→shame/expectancy→performance), regardless of nAch. These data indicate that the total indirect influence from all attributional sources (disregarding algebraic signs) via expectancy is .136 and .045 via shame. While no statistical comparisons are possible between direct and indirect pathways, it is clear that expectancy ($P = .333$) and, to a lesser extent, shame ($P = .131$) exert a considerable direct influence on performance, independent of attributions, whereas, contrary to cognitive theory, variations in expectancy and shame that do depend on attributional mediators have a relatively modest influence on performance.

With the completion of the path analysis of performance, we come full circle, having investigated the entire presumed causal network among all elements of the cognitive model. Whether or not the magnitude of the various attributional influences, both direct and indirect, is sufficient to justify the cognitive theory of achievement motivation in its present form is a major question raised by this study. The results of incremental *F* tests presented in Table 4 help put this question in perspective. Need achievement accounts for some 14% of the explained variation in performance, $F(1, 198) = 4.89$, $p < .05$, through both its direct and indirect influences. The combined attributional sources account for an additional 10%, $F(4, 198) = .90$, $p < .50$. Expectancy, $F(1, 198) = 23.61$, $p < .05$, and shame, $F(1, 198) = 3.71$ $p < .06$, account for the remaining explained variance in performance, 66% and 10%, respectively, and in conjunction with nAch explain 90% of the total R^2. Once again, the data were reanalyzed excluding nAch. The removal of nAch does not appreciably decrease the total R^2 for performance, $F(1, 198) = 1.41$, $p < .25$. But neither is there a corresponding increase in the predictive power of attributions, $F(1, 199) = 1.01$,

$p < .50$. Cognitions, which now account for 14% of the total R^2, as compared to the original 10%, continue to exert only a negligible impact on performance through both direct and indirect pathways, $F(4, 199) = 1.20$, $p < .50$. It is expectancy that gains as a determinant of retest performance, from 66% to 77%, when nAch is removed. This is due to the considerable predictive power shared by nAch and expectancy in the full model.

Another approach for judging the importance of attributions is to assess the predictive power of the traditional theory of achievement motivation in the absence of mediating cognitions. In its simplest form Atkinson's model (1957, 1964) postulates that the performance of any individual depends on a multiplicative combination of achievement motivation (nAch), the incentive value (I_s) of the task (transliterated in Weiner's system as shame), and expectancy of future success (P_s). The final entry in Table 4 indicates that when these basic elements are combined along with attributions, a total of 15.3% of the variance in retest performance is explained. When the identical path analysis is repeated, but this time with all attributional sources removed, 14.8% of the variance remains accounted for, a decrease in explained variance that does not reach statistical significance, $F(4, 198) = 1.17$, $p < .50$. It appears that knowledge of causal ascriptions in failure tells us little more about the quality of subsequent performance than is already known from the elements of the traditional model.

General Discussion

The overall results of this study offer little support for the cognitive model of achievement behavior as presently formulated. First, achievement motive groups do not differ in test performance primarily as a consequence of differential attributions made for a previous failure. Second, although some attributions (notably effort and ability) do contribute to negative affect and future expectancy, these causal relationships are not always in the prescribed direction. Moreover, the effects of attributions on performance as mediated through expectancy and affect are disappointingly small. Third, nAch emerges as an important influence on achievement behaviors in its own right. In the case of shame, nAch contributes both independent of and in common with mediating cognitions, primarily ability. Moreover, nAch exerts a direct impact on expectancy in the absence of a significant contribution from attributions. And finally, nAch affects subsequent performance through a combination of direct influence and indirect influence mediated largely by expectancy, a network basically unaffected by cognitions. We agree with Weiner's recent reassessment that "the presumed causal biases ascribed to individual differences in . . . achievement needs remain somewhat tenuous" (Weiner et al., 1978).

What part, then, if any, do attributions play in the achievement dynamic? In our view, attributions, expressed postdictively, are reactions to rather than causes of performance. As postdictive reactions to failure, attributions are prone to reflect defensive, self-serving biases (Miller, 1976; Snyder, Stephan, & Rosenfield, 1976; Stephan, Rosenfield, & Stephan, 1976; Covington & Omelich, Note 3) and thereby obscure their causal role as information-processing determinants of subsequent achievement behavior. We do not deny the importance of rational considerations in achievement behavior, nor do we argue that self-perceptions of ability and effort ("power" and "try" in Heider's terms) are unimportant. We only suggest that such factors presently represented in the cognitive model as postdictive explanations of success and failure should be relocated as exogenous, antecedent determinants of achievement behavior where they are less likely to be confounded by self-serving tendencies.

The present data strengthen the case for differential self-perceptions of ability as the primary ingredient in achievement motivation (Kukla, 1972a, 1972b; Moulton, 1974; Nicholls, 1976). First, there is a substantial correlation between the Brookover Self-concept of Ability Scale (Brookover, LePere, Hanachek, Thomas, & Erickson, 1965) and the present index of resultant achievement motivation ($r = .44$, $p < .01$). Second, inspection of Figure 2 indicates that despite the

likely presence of self-serving bias, ability nonetheless emerges as the only attribution that links the entire model from nAch to retest performance (via shame). This finding strengthens the conceptual basis for recent work on learned helplessness that focuses on the ability→performance pathway (Abramson, Seligman, & Teasdale, 1978; Dweck, 1977; Covington & Omelich, Note 7).

The central importance of perceived ability to all achievement behavior, including affect and self-confidence, is underscored in a recently proposed self-worth theory of achievement motivation (Beery, 1975; Covington & Beery, 1976) holding that students attempt to maintain and promote self-ascriptions to high ability owing to society's tendency to equate worth with the ability to achieve competitively. In this self-serving process, attributions may not always reflect rational considerations. For example, Covington and Omelich (Note 3) found that males with low self-concept of ability devalued the ability of others compared to their own under identical circumstances of failure, whereas females with low self-concept denigrated their abilities beyond what was rationally indicated by the information at hand. The presence of such bias can only act to obscure, not clarify, the predicted relationships between postdictive attributions and shame, expectancy, and outcome. The study by Weiner and Sierad (1975) illustrates how the interjection of defensive attributions (excuses) can completely alter expected performance outcomes. A drug (placebo) alleged to interfere with hand–eye coordination was administered to college subjects of high and low nAch prior to a learning task. Armed with an explanation for potentially poor performance other than inability, low nAch subjects were expected to perform better than usual, while high nAch subjects were expected to perform poorer than usual owing to the presumed interference of the drug with ability. Both predictions were borne out. The authors correctly conclude that the experiment demonstrates the causal influence of cognitions on performance. Yet it illustrates something more. The presence of self-serving excuses, a factor overlooked by both traditional and cognitive theories, can act to confound the usual attributional linkages.

This reconsideration of the role of attributions underscores the need, in Weiner's words, ". . . to specify the conditions under which individuals avoid feedback and information as a self-protecting, coping strategy" (1977). Identifying the circumstances of failure that elicit defensiveness would appear a useful starting point, with special attention to Heider's dictum (1958) that in order for self-serving biases to be effective, they must fit the constraints of reason. In this connection, Covington and Omelich (Note 3) found that individuals aggrandize their own ability at the expense of others only when such self-protective judgments are plausible, either when their failure is accompanied by low effort or when excuses are available to explain why effort did not pay off.

A reinterpretation of the present data from a self-worth/ability perspective, corroborated by evidence from related sources, provides a glimpse of the complex interaction between affective, social, and cognitive factors in the achievement context. Consider first the dynamics of low nAch students as reflected in Figure 2. Owing to perennial self-doubts about their ability, failure elicits cognitions of incompetency that, in turn, cause shame (low nAch→low ability→shame), a dynamic confirmed independently by laboratory studies (Covington & Omelich, 1979; Sohn, 1977). Shame is further intensified directly through nAch dispositions (low nAch→shame), the linkage originally postulated by Atkinson (1957). This suggests that negative reactions to failure have long been conditioned by a history of failure, irrespective of any implication of low ability. A third source of shame depends on effort level (high effort→shame): effort intensifies shame because high effort/failure is evidence of low ability (Kun & Weiner, 1973) and inferences of inability evoke shame (Covington & Omelich, 1979). While this source of distress may be mitigated temporarily by not studying, as in the case of procrastination (Birney, Burdick, & Teevan, 1969), such tactics are maladaptive in the long run. Students who are perceived by

teachers as having studied little are rewarded less in success and punished more in failure than those students who do try (Rest et al., 1973; Weiner, 1972, 1974). Moreover, according to the present data configuration, low effort may also act to depress retest performance in two interlocking ways. First, low effort contributes to reduced shame (Covington & Omelich, 1979), which in turn tends to decrease performance, presumably to the extent that chagrin might otherwise mobilize effort (Weiner, 1974; Weiner et al., 1971). Second, low effort acts indirectly to suppress performance through lowered expectations of future success (low effort→low expectancy→ low performance). Unfortunately, the low nAch student who works hard is unlikely to fare much better even with the teacher approval that comes from trying. Studying typically occurs in the face of poor prospects for success (low nAch→low expectations), and the likelihood of failure despite high effort simply intensifies the threat to self-esteem as further evidence of low ability (Covington & Beery, 1976). Little wonder that the study habits of low nAch persons have been characterized as conflicted, tense, and ineffectual (Wine, Note 5).

Figure 2 explicates an entirely different dynamic in the case of high nAch individuals. These students tend to experience less distress in failure both because, as predicted by Atkinson (1957), they are success-oriented (high nAch→low shame), and because they are secure in their sense of competency (high nAch→high ability→low shame) (Moulton, 1974; Nicholls, 1976). Although the resulting lower level of shame tends to dampen subsequent performance (high nAch→low shame→ low performance), the relatively small magnitude of this negative suppression effect is more than offset by the tendency to maintain a high expectation of success that manifests itself in increased retest performance (high nAch→high expectancy→high performance). From this it can be seen why an occasional failure for the high nAch student gives little cause for self-doubting of ability or for lowered expectations, nor is it likely to precipitate a vicious cycle of self-defeat so common among low nAch pupils.

Conclusion

Progress toward a fuller understanding of achievement behavior will be made only as long as theories are tested in the naturally occurring contexts of achievement. We conclude from the evidence of the present field study that the achievement process is not solely, or even primarily, a manifestation of cognitive attributions. Rather it is most productively viewed as the operation of personality and socially conditioned dispositions emerging from the individual's efforts to protect and enhance a sense of competency. To be sure, these efforts are moderated by rational information-processing principles of the kind originally proposed by Heider and elaborated by Weiner. Indeed, it is this dynamic interaction of cognition and affect that presents the greatest challenge to the researcher and theoretician.

Uncertainty-Reducing Properties of Achievement Tasks

Yaacov Trope
The Hebrew University of Jerusalem, Jerusalem, Israel

Two experiments were conducted to test the idea that choice among achievement tasks depends on the extent to which performance outcomes are expected to reduce uncertainty about one's ability. Two determinants of expected uncertainty reduction were investigated, the diagnosticity of the task at each zone on the ability scale and the person's uncertainty regarding the ability levels in each zone. As in previous research, the preference for a task increased with its overall diagnosticity, that is, its diagnosticity over the entire ability scale. Furthermore, among tasks of equal overall diagnosticity, subjects preferred tasks that were the most diagnostic at the zone where most of their uncertainty was concentrated, irrespective of the location of this zone on the ability scale. It is concluded that subjects selected tasks that would maximize expected reduction of uncertainty about their standing on the ability scale.

A theme running through a considerable amount of social psychological theory and research is the idea that people characteristically strive to gain self-knowledge. Students of social comparison and attribution processes have contended that a wide range of social phenomena, from emotional reactions and attitude change to affiliation and interpersonal communication, are affected by people's underlying need to assess their own attributes accurately (Festinger, 1954; Nisbett & Valins, 1972; Schachter, 1959; Suls & Miller, 1977). This article is concerned with the manifestations of this need in the domain of achievement behavior. More specifically, it focuses on the effects of (a) initial knowledge about one's own ability and (b) ability-relevant information contained in performance outcomes on choice among achievement tasks.

In the last few years, it has been argued that people choose among achievement tasks according to the amount of ability-relevant information they expect to gain from performance outcomes (Trope & Brickman, 1975; Weiner, Frieze, Kukla, Reed, Rest, & Rosenbaum, 1972). In their paper on the informational properties of achievement tasks, Trope and Brickman proposed that the well-documented preference for intermediate-difficulty tasks reflects a strategy of maximizing information about one's ability. This self-assessment interpretation was offered as an alternative to Atkinson's (1957) widely known theory of achievement motivation, which postulates that a choice of tasks where probability of success equals .50 maximizes positive achievement affect. Specifically, Trope and Brickman argued that the amount of ability-relevant information contained in performance outcomes depends on the *diagnosticity* of the task, that is, the extent to which performance outcomes are expected to vary as a function of ability level. The greater the differences in performance among people of different ability levels, the greater the diagnosticity of the task. Ordinarily, the differences between ability levels tend to be greater at intermediate difficulty tasks. However, Trope and Brickman showed that it is possible to construct tasks in which difficulty and diagnosticity vary independently. When

This research was supported by a grant from the Institute for Human Development at the Hebrew University of Jerusalem. The author would like to thank Gitza Freedman and Daphna Kobovy for research assistance.

presented with such tasks, Trope and Brickman's subjects preferred high-diagnosticity to low-diagnosticity tasks, irrespective of whether the tasks were of intermediate difficulty. The effect of diagnosticity was replicated and extended in subsequent studies (Trope, 1975; Zuckerman, Brown, Fischler, Fox, Lathin, & Minasian, in press; Buckert, Meyer, & Schmalt, Note 1).

In addition to task characteristics (such as diagnosticity), the amount of prior knowledge about one's ability should also affect information gain. A person who has little prior uncertainty about his or her ability level cannot expect to gain much new information from performing tasks low or high in diagnosticity. As uncertainty about one's ability increases, the amount of information the individual can gain should also increase. The notion that uncertainty instigates information seeking is not new to psychology. Extensive research has demonstrated that in various domains, prior to choosing from among several alternatives, the amount of information seeking is directly proportional to the amount of uncertainty regarding the "correctness" of the alternatives (Lanzetta, 1963; Lanzetta & Driscoll, 1968). Lanzetta's research was guided by Berlyne's theory of curiosity (1960), which assumes that uncertainty has drive properties and postulates information seeking as the primary instrumental means for reducing the drive. Now, if achievement behavior is an instance of information seeking in general, we would expect that the more similar the subjective prior probabilities of possessing the various ability levels (i.e., the probabilities held by the person prior to task performance), the greater the uncertainty, and therefore the greater the tendency to perform a relevant task.

A recent study by Trope (Note 2) tested these propositions. Subjects first performed two tasks, each pertaining to a different ability. In one of the experimental conditions, the results were predetermined so as to induce very little uncertainty about their standing on one ability (low-uncertainty ability) and a great deal of uncertainty about their standing on the other ability (high-uncertainty ability). Subjects could then decide whether to continue working on tasks that were relevant to the low-uncertainty ability or on tasks that were relevant to the high-uncertainty ability. As expected, subjects preferred the latter. These tasks were equally attractive in the conditions in which prior results induced the same amount of uncertainty, low or high, about the two abilities.

In the preceding discussion of uncertainty and diagnosticity, the ability dimension was considered as a whole. However, uncertainty and diagnosticity may vary from one zone to another on the ability dimension. Thus, the prior probabilities of the ability levels within one zone may be *higher* and more nearly *equal* than the prior probabilities of the ability levels within another zone. To illustrate, suppose that two zones are considered, the lower half and the upper half of the ability dimension, and imagine a person who is almost certain that he or she is not in the lower zone of the ability dimension but is highly uncertain about his or her location within the upper zone. In probabilistic terms, compared to the ability levels within the lower zone, the ability levels within the upper zone have high and equal prior probabilities. The opposite case would obtain for an individual who is quite sure of not belonging to the upper zone but is unsure as to his or her standing within the lower zone of the ability dimension. That is, the prior probabilities within the lower zone are high and equally distributed among the ability levels. Clearly, these two persons have the same amount of overall uncertainty, but their uncertainty is distributed differently between the two zones: Most of one person's uncertainty is concentrated within the lower zone, whereas most of the other's uncertainty is concentrated within the upper zone.

The amount of information these hypothetical persons can gain from task performance depends on the accuracy with which the task can diagnose (or discriminate between) ability levels within each of the zones. Tasks of equal overall diagnosticity (i.e., equal total amount of variation in performance across all ability levels) may differ in the way their diagnosticity is distributed among the zones. The task may be (a) more diagnostic in the lower zone, producing greater differences in performance among ability levels within the lower zone than among ability levels within

the upper zone (e.g., a task in which performance is a monotone negatively accelerated function of ability); (b) it may be equally diagnostic in the two zones (e.g., a task in which performance is a linear function of ability); or (c) it may be more diagnostic in the upper zone (e.g., a task in which performance is a monotone positively accelerated function of ability).

One can maximize information gain or uncertainty reduction by choosing a task that is most diagnostic at the zone where one's uncertainty is concentrated. That is, information gain depends on the similarity between the distributions of uncertainty and diagnosticity across the various zones of the ability dimension. Hence, the self-assessment notion would predict that a person whose uncertainty is concentrated in the lower zone will be more interested in a task that is more diagnostic in the lower zone, less interested in a task that is equally diagnostic in the two zones, and least interested in a task that is more diagnostic in the upper zone. A person whose uncertainty is concentrated in the upper zone will display the reverse pattern of preferences.

The foregoing analysis was tested in two experiments. Experiment 1 manipulated two variables. The first variable was the subjects' distribution of uncertainty, that is, subjects' uncertainty was concentrated either in the lower zone or upper zone. The second variable was the distribution of task diagnosticity, that is, tasks were more diagnostic within the lower or upper zone or were equally diagnostic within the lower and upper zones. The tasks were equated on overall diagnosticity and difficulty. The second experiment manipulated these last two variables as well as the distribution of diagnosticity. In this experiment, the distribution of uncertainty was inferred from subjects' own beliefs about their ability rather than being experimentally manipulated.

Experiment 1

Method

Subjects

The subjects were 60 male candidates for an officers training school in the Israeli Defense Forces. They participated in the experiment during their stay in an officer selection unit located in an army base. All of the subjects were in regular army service, had completed high school education, and were 18–21 years old.

Procedure and Manipulations

Subjects participated individually in two experimental sessions. In the first, they performed a cognitive task and received predetermined feedback that was designed to manipulate the uncertainty distribution over the relevant ability dimension. In the second session, subjects were presented with three additional tasks varying in diagnosticity distribution over the ability dimension. Subjects then indicated their preferences among these tasks and answered several questions that served as manipulation checks.

At the beginning of the first session, subjects were told that they were taking part in a survey on conceptual ability carried out by the Department of Psychology at the Hebrew University. The experimenter (a civilian) emphasized that subjects' results were anonymous and would not be given to any army authority. Subjects were then informed that their first task would be to perform a test of conceptual ability called "common features test." The test consisted of 20 items in each of which subjects had to name a feature or concept that most precisely fitted a group of four words (e.g., fog, snow storm, electricity blackout, military coup).

After completing the test, subjects were handed a page containing information about conceptual ability and the scoring of the common features test. Subjects read:

> Conceptual ability is manifested in the ability to discover and generate conceptions and rules underlying sets of items of information. Extensive research has shown that young adults with high school education can be classified into three levels of conceptual ability: a relatively low level, a relatively high level, and an intermediate level of conceptual ability which lies halfway between the low and the high levels.

To minimize differences among subjects in prior beliefs about their ability, the statement further noted, "Conceptual ability is not measured adequately by standard intelligence tests. However, previous research has shown that approximately one third of the population of young adults with high school education has each of the three levels of conceptual ability." Subjects were told that the tester examined each answer and determined according to several well-established criteria whether it reflected a low level, an intermediate level, or a high level of conceptual ability.

Manipulation of uncertainty distribution. While the subject was reading this information, the experimenter pretended to score his test, ostensibly using an impressive table of norms and categories. The experimenter presented the results on a results sheet.

Table 1
Experiment 1: Reported Mean Percentages of Correct Items as a Function of Ability Level, Uncertainty Distribution, and Diagnosticity Distribution

Ability level	Uncertainty distribution: Descending — Diagnosticity distribution: Descending	Descending — Constant	Descending — Ascending	Ascending — Descending	Ascending — Constant	Ascending — Ascending
Low	29.8	37	44.2	15.8	23	30.2
Intermediate	65.8	57	48.2	51.8	43	34.2
High	69.8	77	84.2	55.8	63	70.2

In one condition, the results sheet indicated that out of the 20 answers, 9 (45%) reflected low ability, 9 (45%) intermediate ability, and 2 (10%) high ability. These results were designed to induce high probabilities of the low and the intermediate levels and a low probability of the high level. In the other condition, the results sheet indicated that 2 answers (10%) reflected low ability, 9 (45%) intermediate ability, and 9 (45%) high ability. These results were designed to induce a low probability of the low level and high probabilities of the intermediate and high levels. The former condition is referred to as *descending uncertainty* condition, meaning that most of the uncertainty was concentrated in the low half of the ability scale; the latter condition is referred to as *ascending uncertainty*, meaning that most of the uncertainty was concentrated in the upper half of the ability scale. Thirty subjects were randomly assigned to each condition.

After receiving the results, subjects were escorted to an adjacent room where another experimenter conducted the second session. This experimenter told subjects that he would like them to work on a test of conceptual ability called "classification test" and that they would receive their results. Subjects were told that each item in the test presented a list of objects or events that had to be assigned into four mutually exclusive classes. It was further indicated that there was only one correct classification and that the score on the test was the percentage of items correctly solved. Subjects were informed that the test consisted of three subtests, 30 items in each, with the kind of elements to be classified—words, figures, or letters—varying from subtest to subtest.

Manipulation of diagnosticity distribution. The subject was then shown a visual display of fictitious results that the low, intermediate, and high ability groups purportedly achieve at each of the subtests. Each subtest was represented by a diagram that displayed on a horizontal 0% to 100% scale the mean performance of each ability group and the interval within which the performance of 90% of the group fell. Table 1 presents the means for each subtest in the descending and ascending uncertainty conditions. All the intervals were 30% wide and symmetric around the means.

The following constraints were employed in deriving these means. In order to hold overall diagnosticity constant, the difference between the means of the lowest and highest ability groups was set at 40% in all of the subtests. Another set of constraints was designed to manipulate diagnosticity distribution. In subtests that were more diagnostic at the lower half of the ability scale, referred to as *descending diagnosticity* subtests, the difference between the low and intermediate levels was set nine times as great as the difference between the intermediate and high levels. In the subtests that were more diagnostic at the upper half of the ability scale—*ascending diagnosticity* subtests—the magnitude of these two differences was reversed. In subtests that were equally diagnostic at the lower and upper halves of the scale—*constant diagnosticity* subtests—these two differences were of the same magnitude. The third constraint was on expected performance at the subtests and was designed to hold perceived difficulty constant. Expected performance on a test was defined as the overall mean of the performances of the three ability levels, each weighted by the probability of having the corresponding ability level. Obviously, these probabilities should be different in the two uncertainty distribution conditions. In fact, pretesting indicated that the probabilities assessed by subjects were quite close to the proportions of answers in the common features test that purportedly reflected each ability level. Hence, the prior probabilities of the low, intermediate, and high ability levels were assumed to be .45, .45, and .10, respectively, in the descending uncertainty condition and .10, .45, and .45, respectively, in the ascending uncertainty condition. Using these probabilities, expected performance at the three subtests was set at 50% in the two uncertainty distribution conditions.

The order of presentation of the diagrams for the three subtests was varied across subjects according to a 3×3 Latin square design.

Measures. Subjects were informed that they were to choose a total of 28 items to work on and that they could decide how many items would come from each subtest. After indicating their selection of items, subjects were asked to fill out an evaluation questionnaire while the experimenter was ostensibly pre-

paring the test material. The first set of questions in this questionnaire pertained to the three subtests of the classification test. Subjects rated five questions on 7-point scales: (a) their willingness to work on each subtest, (b) their interest in finding out how they would perform at each subtest, (c) the accuracy with which each subtest could discriminate between the low and the intermediate levels of ability, (d) the accuracy with which each subtest could discriminate between the intermediate and the high levels of ability, and (e) the difficulty of each subtest. Questions a and b, together with the measure of item selection, served as measures of task preference. Questions c and d served as checks on the manipulation of diagnosticity distribution. Question e was designed to check the assumption that the subtests were equated on perceived difficulty. As a check on the manipulation of uncertainty distribution, subjects were asked to rate on three 11-point scales (ranging from 0 to 100) the chances of their having each of the three ability levels. After subjects had completed the questionnaire, the experiment was terminated. The experimenter thoroughly debriefed the subjects, checking for suspicion and explaining the actual purpose of the study and the reason for the deceptions.

Results and Discussion

Manipulation Checks

The manipulation of uncertainty distribution (i.e., the feedback from the common features test) had a strong effect on subjects' assessments of the probabilities of having each ability level. In the descending uncertainty condition, the means of the probabilities of the low, intermediate, and high levels were .36, .43, and .21, respectively, and in the ascending uncertainty condition, they were .10, .43, and .47. An analysis of variance (Uncertainty Distribution × Ability Level) yielded a highly significant interaction, $F(2, 116) = 65.07$, $p < .001$, indicating that in the descending uncertainty condition, the difference between the low and intermediate levels was small and insignificant and the difference between the intermediate and high levels large and significant ($p < .001$), whereas in the ascending uncertainty condition, the former difference was large and significant ($p < .001$), and the latter small and insignificant. Hence, as intended, in the descending uncertainty condition most of the uncertainty concerned the low and intermediate levels (i.e., the lower half of the ability scale), whereas in the ascending uncertainty condition most of the uncertainty concerned the intermediate and high levels (i.e., the upper half of the ability scale). It should be noted, however, that although the two conditions differed in the expected direction, the uncertainty distribution in the ascending uncertainty condition was more in line with the feedback from the common features test than it was in the descending uncertainty condition. In the latter condition, therefore, the uncertainty was more evenly distributed over the ability scale.

The first two rows in Table 2 indicate that the manipulation of diagnosticity distribution was successful. As expected, descending diagnosticity tests were perceived as the most accurate and the ascending diagnosticity tests as the least accurate in discriminating between low and intermediate ability. On accuracy in discriminating between intermediate and high ability, the ordering of the subtests was reversed. Analyses of variance (Uncertainty Distribution × Diagnosticity Distribution) supported these observations, yielding highly significant effects of diagnosticity distribution on ratings regarding accuracy of discrimination between low and intermediate ability, $F(2, 116) = 68.27$, $p < .001$, and between intermediate and high ability, $F(2, 116) = 52.08$, $p < .001$. No other source of variation was significant in these analyses. Finally, as intended, the perceived difficulty of the subtests (Row 3, Table 2) did not significantly vary as a function of the experimental variables. It seems, then, that the fact that expected performance was kept constant [1] made the subtests appear equally difficult.

Choice and Preference Among Subtests

The number of items selected from each subtest served as the main dependent variable. The pertinent means in Figure 1 indicate that the manipulation of uncertainty distribution produced two opposite combinations of items from the three subtests. As pre-

[1] As noted above, the subjective probabilities of the ability levels in the descending uncertainty condition somewhat deviated from the reported proportions of items that purportedly indicated the various ability levels. Even if these probabilities are used to calculate expected performance, however, the differences among the subtests remain extremely small.

Table 2
Experiment 1: Mean Ratings of Tasks as a Function of Uncertainty Distribution and Diagnosticity Distribution

Measure	Uncertainty distribution: Descending; Diagnosticity distribution: Descending	Descending; Constant	Descending; Ascending	Ascending; Diagnosticity distribution: Descending	Ascending; Constant	Ascending; Ascending
Accuracy in discriminating between low and intermediate ability	5.87	4.50	2.50	5.57	4.20	2.50
Accuracy in discriminating between intermediate and high ability	2.90	4.80	5.70	2.90	4.20	6.27
Difficulty	3.45	3.38	3.99	3.37	3.07	3.80
Willingness to work on subtest	5.23	4.50	3.53	3.63	3.93	5.47
Interest in finding out results	5.93	5.33	4.97	4.37	4.80	6.27

dicted, in the descending uncertainty condition the greatest number of items came from the descending diagnosticity subtest and the smallest from the ascending diagnosticity subtest, whereas in the ascending uncertainty condition the results were reversed. This dependency of choice among subtests on uncertainty distribution was reflected in a strong Uncertainty Distribution × Diagnosticity Distribution interaction effect, $F(2, 116) = 13.56$, $p < .001$, which was the only significant source of variation.

The same picture emerges from the ratings of desire to work on the subtests (Table 2, row 4) and the ratings of interest in finding out the results of performance at the subtests [2] (Table 2, row 5). Analyses of variance of these ratings yielded highly significant Uncertainty Distribution × Diagnosticity Distribution interaction effects ($p < .001$), with no other effect being significant. It is particularly interesting that the main effects of uncertainty distribution were insignificant ($F < 1$), meaning that subjects in the two uncertainty distribution conditions had the same overall interest in working on the subtests and in finding out how they would perform.

Finally, it seems that the slopes relating item selection and the preference ratings to diagnosticity distribution are steeper in the ascending uncertainty condition than in the descending uncertainty condition. The F ratios corresponding to these comparisons were insignificant, but it is worth noting that this difference in slopes may be due to the fact, indicated earlier, that in the descending uncertainty condition subjects' uncertainty was more evenly distributed between the two halves of the ability scale.

In conclusion, subjects' choice behavior suggests that they systematically employed a strategy of maximizing information about their ability. The descending uncertainty and the ascending uncertainty groups did not differ in this respect. First, the two groups expressed the same overall amount of interest in the ability-relevant tasks. Second, both groups were interested in working on a task to the extent that its diagnosticity distribution fitted their uncertainty distribution. Thus, subjecs were most interested in a task that was highly diagnostic at the ability zone where their uncertainty was concentrated, irrespective of the location of this zone on the ability dimension.

[2] The correlations between the three dependent variables (the two ratings and items selection) *within* conditions ranged from .42 to .79, with a mean of .56.

Experiment 2

This experiment manipulated three variables: overall diagnosticity, diagnosticity distribution, and difficulty. The first and last of these variables were held constant in Experiment 1. Distribution of uncertainty, which was experimentally manipulated in Experiment 1, was inferred in this experiment from subjects' assessments of their own ability level. It was assumed that the higher the perceived ability, the higher the zones on the ability dimension within which the uncertainty was concentrated.

Method

Subjects

The subjects were 54 male soldiers who belonged to the same population from which the subjects of Experiment 1 were drawn.

Procedure and Manipulations

Subjects participated in the experiments in groups ranging in size from three to five. The experimenter stated that the purpose of the study was to investigate opinions and feelings about ability tests. As in Experiment 1, subjects were assured that their answers were anonymous. The experimenter then handed the subjects a booklet titled *Survey of Opinions about Tests of Mental Concentration.* In the booklet subjects read that they would receive information about several tests of mental concentration in all of which the testee had to solve a series of items within a certain time limit. It was indicated that the tests varied in the type of item they included —numerical, verbal, or figural—and in emphasis on perception, memory, or reasoning. Subjects were then informed that extensive research had shown that young adults with high school education could be classified into seven levels of mental concentration, with approximately 14% of this population belonging to each of the levels.

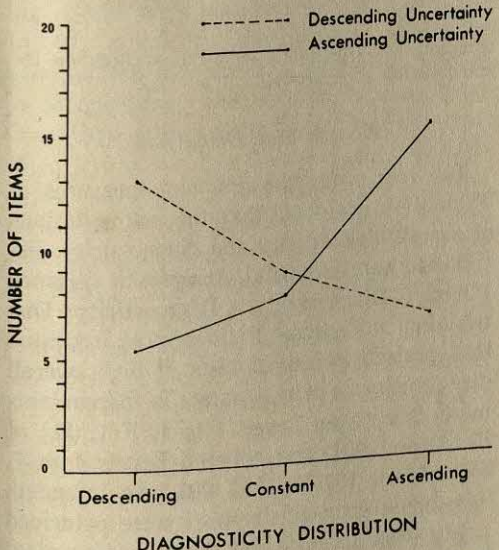

Figure 1. Experiment 1: Mean number of items selected from each test as a function of uncertainty distribution (descending uncertainty vs. ascending uncertainty) and diagnosticity distribution (descending vs. constant vs. ascending).

At this point, subjects were asked to assess their own level of mental concentration. Subjects were given a seven-interval scale with labels from Level 1 (lowest ability) to Level 7 (highest ability) and were asked to indicate their level of ability.

The booklet then indicated that previous research had obtained a large amount of data on the results that are typically achieved by people of different levels of mental concentration. An example of such data for one of the tests was then presented. Each ability level was represented by a bar whose height indicated the average percentage of correctly solved items. The bars, from left to right, indicated the lowest to highest ability levels, and were labeled beneath from 1 to 7, respectively. In this example, the average of Level 1 was 35%, which increased linearly with ability level up to 65% in Level 7. Subjects were told that in this test as well as in the other tests, the performance of 90% of each ability level lay between 4% below the average to 4% above the average.

Manipulation of test characteristics. After completing the example, each subject considered six tests varying in overall diagnosticity and distribution of diagnosticity. Each test was represented by a bar graph, as in the example. In tests of high overall diagnosticity the difference in performance between Level 1 and Level 7 (51%) was three times as great as the corresponding difference in tests of low overall diagnosticity (17%). The three tests within each level of overall diagnosticity varied in distribution of diagnosticity. Thus, the difference between Levels 1 and 7 (or overall diagnosticity) was divided such that the difference between Levels 1 and 4 (or diagnosticity at the lower half of the ability scale) was either greater, smaller, or equal to the difference between Levels 4 and 7 (or diagnosticity at the upper half of the ability scale). In the descending diagnosticity test the difference between Levels 1 and 4 was 7.5 times greater than the difference between Levels 4 and 7. In the ascending diagnosticity test the magnitude of these differences was reversed. In the constant diagnosticity test these differences were of the same magnitude. Within each half of the ability scale, performance was linearly related to ability level. Difficulty was manipulated by varying expected performance on the tests, that is, the overall mean of

	5	64.38	62.83	61.30	73.14	68.50	63.86
	6	65.05	65.66	66.30	75.14	77.00	78.86
	7	65.72	68.50	71.30	77.14	85.50	93.86

performance across the seven ability levels. There were three levels of expected performance: 40%, 50%, and 60%. The percentages presented to subjects in the bar graphs (see Table 3) were derived by using these constraints.

Expected performance was manipulated between subjects. Twenty subjects were randomly assigned to each of the three expected performance conditions. Each group considered six tests (varying in overall diagnosticity and diagnosticity distribution) with order of presentation varying across subjects according to a 6×6 Latin square design.

Measures. Subjects rated seven questions on 11-point scales: (a) their willingness to work on each test; (b) the attractiveness of each test; (c) their interest in finding out how they would perform at each test; (d) the accuracy with which each test could discriminate between Levels 1, 2, 3, and 4 of mental concentration; (e) the accuracy with which each test could discriminate between Levels 4, 5, 6, and 7 of mental concentration; (f) the accuracy with which each test could reveal their level of mental concentration; and (g) the difficulty of each test. Questions a to c served as measures of task preference. Questions d to f served as checks on the manipulations of overall diagnosticity and diagnosticity distribution, and Question g served as a check on the manipulation of difficulty.

Results and Discussion

The results for the first two measures in Table 4 clearly show that the manipulations of overall diagnosticity and diagnosticity distribution were successful. Analyses of variance (Overall Diagnosticity $\times$ Diagnosticity Distribution $\times$ Expected Performance) indicated that subjects perceived tests of high overall diagnosticity as more accurate in discriminating both between Levels 1 to 4, $F(1, 51) = 69.63$, $p < .001$, and between Levels 4 to 7, $F(1, 51) = 152.73$, $p < .001$. As intended, descending diagnosticity tests were perceived as the most accurate and the ascending diagnosticity tests as the least accurate in discriminating between Levels 1 to 4, $F(2, 102) = 155.95$, $p < .001$, whereas on accuracy in discriminating between Levels 4 to 7, the order-

ing of the tests was reversed, $F(2, 102) = 112.07$, $p < .001$. Furthermore, since the *manipulated* differences among tests varying in diagnosticity distribution were greater when their overall diagnosticity was high than when it was low (see Table 3), the two variables were expected and found to have interactive effects on perceived accuracy in discriminating between Levels 1 to 4, $F(2, 102) = 18.17$, $p < .001$, and between Levels 4 to 7, $F(2, 102) = 13.06$, $p < .001$.

While expected performance did not have any effect on the ratings of perceived diagnosticity, it had a marginally significant effect on perceived difficulty (see fourth measure, Table 4), indicating that the higher the expected performance at the test, the easier the test, $F(2, 51) = 2.87$, $p < .07$. The only other significant effect on perceived difficulty was a Diagnosticity Distribution × Expected Performance interaction, $F(4, 102) = 2.94$, $p < .05$, which was unexpected and hard to interpret.

Prior to discussing the other measures, subjects' reports about their level of mental concentration should be considered. Quite surprisingly, the range of reported ability levels was extremely narrow. No subjects reported an ability below Level 4; only 2 subjects reported Level 4, 25 reported Level 5, 21 reported Level 6, and only 6 reported Level 7. These data suggest that the uncertainty of most of the subjects was confined to the high ability levels. It follows that subjects should rate the accuracy with which a test can determine their *own* ability according to the degree to which it can discriminate between the high levels, that is, the ascending diagnosticity tests should be rated highest and the descending diagnosticity tests lowest. The pertinent data in Table 4 (third measure) fully corroborated this predicted effect of diagnosticity distribution, $F(2, 102) = 49.26$, $p < .001$. Furthermore, as intended, ratings of the test's accuracy in determining one's own ability increased with overall diagnosticity, $F(1, 51)$

$= 76.70$, $p < .001$, and the effect of diagnosticity distribution on ratings of tests of high overall diagnosticity was stronger than its effect on ratings of tests of low overall diagnosticity, $F(2, 102) = 20.39$, $p < .001$.

Turning to subjects' preferences among the tests, we should note that the three measures —willingness to work on the test, attractiveness of the test, and interest in finding out the results—correlated highly across subjects for each of the six tests. The mean of the 18 correlations (3 intercorrelations for each of the six tests), using Fisher's r-to-z transformations, was .77. The three measures therefore were averaged (see Table 4, last measure). The self-assessment notion would predict that preferences among tests should be closely related to judgments about their accuracy in determining one's own ability. The means of the index of test preference substantiated this prediction. First, tests of high overall diagnosticity were preferred to tests of low overall diagnosticity, $F(1, 51) = 40.55$, $p < .001$. Second, there was a strong effect of diagnosticity distribution, $F(2, 102) = 26.99$, $p < .001$, indicating that tests discriminating mainly between high ability levels (ascending diagnosticity tests) were preferred to tests that discriminated equally between all levels (constant diagnosticity tests), which in turn were preferred to tests that discriminated mainly between low ability levels (descending diagnosticity tests). Third, this effect of diagnosticity distribution was more pronounced when overall diagnosticity was high than when it was low,[3] $F(2, 102) = 7.44$, $p < .001$. In none of these analyses did expected performance (or difficulty) have a significant effect on ratings. Finally, the close relationship between test preference and perceived accuracy in determining one's ability was reflected in the correlations between the two measures across subjects for each of the tests. All these correlations were highly significant, ranging from .415 to .674, with a mean of .55 (using Fisher's r-to-z transformations).

The effects of uncertainty distribution on task preference could not be fully manifested in this experiment because, as noted above, the ability levels that the subjects reported implied that their uncertainty was concentrated in the upper region of the ability dimension. However, this may be less true for subjects who reported the more moderate levels (i.e., Levels 4 and 5). It seems plausible that these subjects assigned higher probabilities to the low ability levels than did subjects who reported extremely high levels (i.e., Levels 6 and 7). In that case, the former group's uncertainty was more evenly distributed over the ability scale. Such uncertainty distribution should act to increase their interest in tests that can discriminate between low ability levels, namely, descending and constant diagnosticity tests. More precisely, the self-assessment notion would predict that the preference for ascending diagnosticity tests over constant and descending diagnosticity tests would be more pronounced among extremely high ability subjects than it would be among moderately high ability subjects.

Figure 2 presents means of the index of test preferences for subjects whose perceived ability was below the median (Levels 4 and 5) and for subjects whose perceived ability was above the median (Levels 6 and 7). It can be seen that the preferences of the extremely high ability group increased from the descending to the ascending diagnosticity test much more sharply than did the preferences of the moderately high ability group, $F(2, 104) = 14.62$, $p < .001$, for the Perceived Ability × Diagnosticity Distribution interaction. Moreover, this difference between the two perceived ability groups was greater with respect to tests of high overall diagnosticity than with respect to tests of low overall diagnosticity, $F(2, 104) = 3.03$, $p < .06$, for the Overall Diagnosticity × Perceived Ability × Diagnosticity Distribution interaction. Figure 2 also suggests an interaction between perceived ability and overall diagnosticity, $F(1, 52) = 8.23$, $p < .025$, which, unlike the other interactions involving perceived ability, was not derived from the self-assessment notion. This interaction suggests that among extremely high ability subjects the preference for high diagnosticity tests over low diagnosticity tests

[3] The same significant effects were obtained in separate analyses of each of the three measures of test preference.

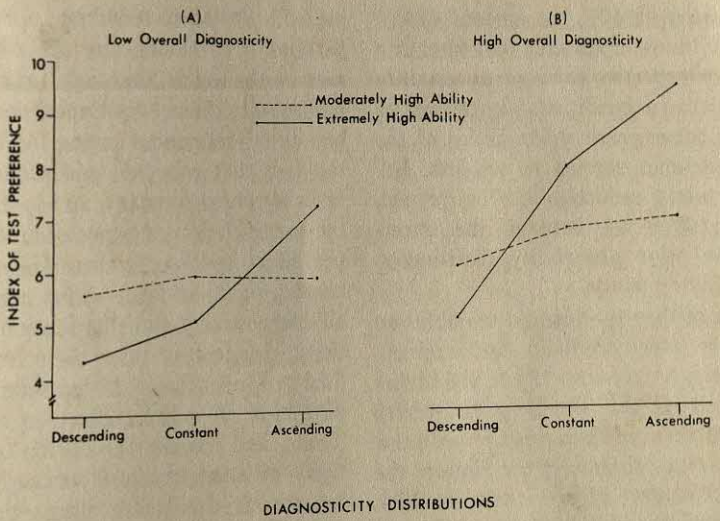

Figure 2. Experiment 2: Means of the index of test preference as a function of perceived ability (moderately high ability vs. extremely high ability), overall diagnosticity (low vs. high), and diagnosticity distribution (descending vs. constant vs. ascending).

was more pronounced than among moderately high ability subjects. It should be noted, however, that perceived ability did not have a significant main effect, that is, it did not affect overall interest in the tests.

General Discussion

The present experiments tested the idea that people choose among tasks according to the amount of ability-relevant information they expect to gain. Two general determinants of information gain were considered: the person's initial knowledge about his or her ability and the informational properties of the task. The former determinant was represented by distribution of uncertainty and the latter by overall diagnosticity and its distribution. On the whole, the effects of these variables on task preference supported the hypotheses and can be summarized as follows. First, as in previous research, tasks of high overall diagnosticity were preferred to those of low overall diagnosticity (Trope, 1975; Trope & Brickman, 1975; Zuckerman et al., in press; Buckert et al., Note 1). Second, with overall diagnosticity held constant, preferences were determined jointly by uncertainty distribution and diagnosticity distribution, that is, subjects preferred tasks that could most accurately diagnose within the zone where their uncertainty was concentrated. Third, the joint effect of uncertainty and diagnosticity distributions was more pronounced when overall diagnosticity was high than when it was low, as overall diagnosticity was manipulated as a multiplier of diagnosticity in each zone.

These results seem to reflect a preference for tasks that can add to previously acquired knowledge about one's own ability. Thus, when subjects could infer from previous performance that they were most likely to have, for example, one of the relatively high ability levels, they wanted to work on a task that could determine with precision which of these levels they actually had. These subjects were least interested in a task that made precise discriminations only between the low ability levels, which they were unlikely to have. Such a task would only reaffirm that they possessed one of the high ability levels.

Moreover, the observed task preferences conform to what a normative model of uncertainty reduction would prescribe. In such a model, each outcome revises prior probabilities of the ability levels into posterior probabilities (see Trope & Brickman, 1975). From each of these posterior probability distributions, it is possible to derive, as in information

theory (Attneave, 1959), the amount of uncertainty conditional upon each outcome. One can obtain an expected value of uncertainty by summing these conditional uncertainties across all outcomes, with probabilities of the respective outcomes serving as weights. Expected uncertainty reduction can be defined, then, as the difference between the uncertainty in the prior probability distribution and expected uncertainty.

The effects of the experimental variables on choice can be traced to their effects on expected uncertainty reduction. First, the higher the diagnosticity of the outcomes, the greater the amount of revision from prior to posterior probabilities, and therefore the lower the expected uncertainty. Hence, tasks of high overall diagnosticity reduce more uncertainty than tasks of low overall diagnosticity. Second, the distribution of diagnosticity over the zones of ability determines the distribution of diagnosticity over performance outcomes. Assuming that performance is a positive monotone function of ability, it follows that diagnosticity is related to ability and performance outcomes in a similar manner. Thus, if the task is more diagnostic of low ability levels, then relatively low outcomes are more diagnostic, whereas if the task is more diagnostic of high ability levels, then relatively high outcomes are more diagnostic. Third, the distribution of uncertainty affects the probabilities of the outcomes: The higher the zone of ability within which uncertainty is concentrated, the higher the probability of relatively high outcomes and the lower the probability of relatively low outcomes. Now, since the uncertainty reduced by each outcome is weighted by the probability of the outcome, expected uncertainty reduction is high to the extent that outcomes that reduce much uncertainty have high probability and outcomes that reduce little uncertainty have low probability. Clearly, this requirement is fulfilled by tasks that are highly diagnostic in the zone where uncertainty is concentrated. The fact that subjects preferred such tasks suggests that they were interested in maximizing expected uncertainty reduction.

In and of itself, expected performance or task difficulty does not necessarily affect expected uncertainty reduction, nor did subjects perceive it as having any effect on the accuracy with which the tasks could diagnose their ability. Hence, in Experiment 1 subjects had clear preferences among the tasks despite the fact that expected performance at these tasks was held constant, and in Experiment 2 the manipulation of expected uncertainty did not affect task preference. However, in the absence of direct information regarding overall diagnosticity and distribution of diagnosticity, people may infer them from task difficulty. Under these circumstances difficulty may have an indirect effect on choice. Thus, Trope and Brickman (1975) argued that tasks with intermediate success probabilities are perceived as more diagnostic and therefore more attractive than tasks with more extreme probabilities (see also Meyer, Folkes, & Weiner, 1976). Furthermore, it seems probable that easy tasks are perceived as more diagnostic of low ability levels (i.e., poor performance is more diagnostic than good performance) and difficult tasks as more diagnostic of high ability levels (i.e., good performance is more diagnostic than poor performance). Hence, to maximize information gain or uncertainty reduction, people with low perceived ability (whose uncertainty is concentrated in the low ability levels) should prefer relatively easy tasks, whereas people with high perceived ability (whose uncertainty is concentrated in the high ability levels) should prefer more difficult ones. The same logic applies to the case of two outcomes, success and failure, and two levels of ability, low and high. As difficulty increases, the perceived diagnostic value of success becomes greater than that of failure, and since the subjective probability of success increases with perceived ability, people with high perceived ability should prefer more difficult tasks than people with low perceived ability (see Zuckerman et al. for corroborating results). Poor performance shifts the uncertainty to lower ability levels and good performance shifts it to higher ability levels. Hence, in the former case, the person will attempt increasingly easier tasks, whereas in the latter case, he or she will attempt increasingly harder tasks. These well-documented

shifts in "level of aspiration" (Lewin, Dembo, Festinger, & Sears, 1944) are interpreted here as attempts to keep the amount of new ability-relevant information at a maximum.

The present findings are relevant to the view that self-enhancement and self-protective needs (Bradley, 1978; Jones, 1973) determine task choice. Kukla (1978) has recently suggested an attributional theory of choice based on the assumption that the tendency to work on a task increases with the level of ability that performance is expected to imply. A task will be attractive if it can demonstrate one's high ability, but it will be avoided if it may betray one's low ability. With regard to the present study, this approach would predict that subjects who suspect that they have one of the low ability levels will be less interested in working on the ability-relevant tasks than will subjects who believe that they have one of the high ability levels. However, the data did not show any trace of such a main effect of perceived ability (or uncertainty distribution). Furthermore, self-serving biases should produce a preference for a task that is more diagnostic of high ability levels over a task that is more diagnostic of low ability levels. More specifically, persons with high perceived ability should be attracted to the former task because it can demonstrate unequivocally that they have high ability, and persons with low perceived ability should *avoid* the latter task because it may disclose that they have low ability. Again, there was very little evidence for such asymmetry. Subjects chose the task that was diagnostic at the zone of ability within which their uncertainty was concentrated, even when performance of this task could give very unflattering results. Finally, it is worth noting that perceived ability did not produce any self-serving distortions of the informational properties of the tasks. Specifically, subjects with high perceived ability did not overestimate the accuracy with which performance could reveal high ability; nor did subjects with low perceived ability underestimate the accuracy with which performance could reveal poor ability. The judgments of both groups were appropriately related to the manipulated values of the informational characteristics of the tasks.

There was one result, a Perceived Ability × Overall Diagnosticity interaction, which *was* consistent with the self-enhancement view. This interaction indicated that the preference for the high overall diagnosticity tasks was more pronounced among subjects with extremely high perceived ability than among subjects with moderately high perceived ability. This result suggests that subjects' choice behavior was not entirely free from self-serving biases. It should be remembered, however, that in Experiment 2, where this interaction was obtained, perceived ability was varied by subject selection, which leaves open the possibility of a correlated variable. Achievement motive, which was found to be correlated with perceived ability (Kukla, 1978), may be such a variable; previous research by Trope (1975) has shown that high-achievement-motive people are more interested in ability-relevant information than low-achievement-motive subjects. In addition, while Zuckerman et al. obtained a similar effect of perceived ability, Buckert et al. (Note 1) did not. Clearly, more research on this problem is needed before definite conclusions can be reached.

Even if self-serving biases were entirely absent in the data, it would not have meant that our subjects were affectively indifferent to the ability-relevant feedback they received or expected to receive. Extrapolating from previous research on reactions to self-evaluation (see reviews by Bradley, 1978; Jones, 1973; Shrauger, 1975) it seems plausible that the subjects who learned that they had one of the low ability levels were distressed by the feedback and anticipated even greater distress should the next task diagnose a low level of ability. However, the present results cast doubt on the assumption that such affective reactions shape choice strategy. The desire to assess one's ability accurately seems a more powerful determinant of choice, at least under the circumstances investigated in this study. It remains for future research to determine the generalizability of this conclusion to different circumstances. One limiting condition is suggested by the fact that subjects in the present study were assured that their future

performance would remain anonymous. It is possible that when performance is expected to be public, the enhancement of self-esteem as well as social esteem may assume greater importance than accurate self-assessment. In such a situation, people may actually choose to work on tasks that are expected to diagnose their strengths but not their weaknesses.

The Role of Facial Response in the Experience of Emotion

Roger Tourangeau and Phoebe C. Ellsworth
Yale University

Facial expression and emotional stimuli were varied orthogonally in a 3 × 4 factorial design in order to test whether facial expression is necessary or sufficient to influence emotional experience. Subjects watched a film eliciting fear, sadness, or no emotion, while holding their facial muscles in the position characteristic of fear or sadness, or in an effortful but nonemotional grimace; those in a fourth group received no facial instructions. The subjects believed that the study concerned subliminal perception and that the facial positions were necessary to prevent physiological recording artifacts. The films had powerful effects on reported emotions, the facial expressions none. Correlations between facial expression and reported emotion were zero. Sad and fearful subjects showed distinctive patterns of physiological arousal. Facial expression also tended to affect physiological responses in a manner consistent with an effort hypothesis.

Half a century ago, Cannon's decisive critique of the James–Lange theory ended scientific consideration of the hypothesis that peripheral responses provide the basis for qualitative distinctions among emotions. Nonspecific arousal theories have dominated the study of emotion ever since (Duffy, 1934, 1962; Lindsley, 1951). The James–Lange theory (James, 1890; Lange, 1885/1922) proposed that emotional stimuli elicit physiological responses specific to each emotion; the experience of an emotion, according to their view, is the perception of the corresponding physiological pattern.[1] By contrast, the nonspecific arousal theorists argue that physiological patterns do not correspond to specific emotions but only to the intensity of general emotional arousal and perhaps (Duffy, 1962) to a global, primitive approach–avoidance tendency. These theories have little to say about qualitative distinctions among the emotions. They tend to share, implicitly or explicitly, the assumption that such distinctions are the product of learning. The theory of Schachter and Singer (1962), for example, asserts that undifferentiated arousal is classified according to situational cues to determine the emotional experience. Qualitative distinctions derive from the classification; the classification presumably derives from social learning (see also Duffy, 1962).

The learning position of the arousal theorists is cast into some doubt by recent evidence for the widespread cross-cultural gen-

The research reported here was funded by National Science Foundation Grant BNS-75-22890 awarded to the second author. We are grateful for the assistance of Sidney Don and Steven Ganahl, who served as experimenters; Michael Brownstein, Barbara Fleming, Kathy Gould, and Jane Schweitzer, who assisted with scoring the data; Paul Ekman, Wallace V. Friesen, Alison Webb, Adelle Wenning, Nancy Wilner, and the Yale Audio-Visual Center, who helped us find, pretest, and edit the films; and Robert Novelly, who advised us on appropriate physiological measures.

[1] The theories proposed by James and by Lange differ in that Lange's theory was restricted to autonomic feedback (heart rate, stomach contractions, blushes, etc.), whereas that of James also included muscular feedback (such as changes in tonus, posture and, presumably, facial expression). Most subsequent writers, including the major critics, attributed the visceral version to both authors indiscriminately; in using the term "James–Lange theory" we will follow in this tradition, while recognizing that the muscular components of the James theory were not fully discredited by Cannon's research, and have much in common with the later facial feedback hypotheses.

erality of a small set of basic emotion categories, reliably used in labeling facial expressions of emotion (Ekman, Sorenson, & Friesen, 1969; Ekman & Friesen, 1971; Izard, 1971). If emotion categories are learned, cultural phenomena, why should all cultures studied so far share the same small set? In line with the evidence on the cross-cultural generality of the recognition of facial expressions, some theorists (Tomkins, 1962; Izard, 1971, 1977) have proposed that feedback from the facial muscles is important in the subjective experience of emotion. In the strongest version of these facial feedback theories, facial responses play the same critical role as more general visceral and muscular changes play in the James-Lange theory: the proprioception of the facial response *is* the experience of emotion. This shift in emphasis from visceral to facial feedback neutralizes most of Cannon's criticisms of the James–Lange theory. Cannon (1927), for example, argued that visceral responses were too slow and too undifferentiated to be the basis of the subjective experience; facial expressions are sufficiently immediate and sufficiently various; similarly, Cannon's demonstrations of "emotional" behavior in animals whose viscera were separated from their central nervous systems are irrelevant to the facial theories.

Although they differ on the causal priority assigned to each, these various positions predict that in general self-report, facial, and physiological measures of emotion should be positively correlated. In contrast, still another position predicts a negative correlation among these measures. This cathartic–hydraulic view was proposed first by James (1890); its chief exponent, however, is Freud (1946/1921). According to the hydraulic view, verbal, facial, and physiological responses are alternative channels for releasing the emotional energy evoked by a stimulus; if one channel is blocked, the response through the others should increase in intensity.

What is the evidence for the various views? The general arousal models receive a certain amount of indirect support from the numerous failures to find clear patterns corresponding to different emotions (Lacey, Kagan, Lacey, & Moss, 1963; Lindsley, 1951). In addition, Hohmann (1966) has found, contrary to Cannon's (1927) contention, that separation of the viscera from the central nervous system (due to spinal lesions) in humans is associated with reduced emotional responding. Finally, there is Schachter and Singer's (1962) demonstration that induced autonomic arousal can lead to various types of emotional (and unemotional) response (see also Schachter & Wheeler, 1962; Zillman & Bryant, 1974).[2] On the other hand, some of the better studies of emotional arousal *have* found evidence that different emotions are associated with different autonomic patterns (Ax, 1953; Funkenstein, 1955; Wolf & Wolff, 1947). Hohmann's findings on patients with spinal lesions invite numerous interpretations. Schachter and Singer's results do not always replicate (see Marshall & Zimbardo, 1979; Maslach, 1979), and even in their original experiment the differences between subjects given situational cues for euphoria and those given cues for anger were negligible. Finally, Cannon's arguments on the long latencies of visceral responses still pose difficulties for any theory that makes the sensation of autonomic arousal a necessary condition for emotional experience.

The strongest evidence for the facial feedback view comes from studies by Laird (1974) and Lanzetta, Cartwright-Smith, and Kleck (1976). Laird showed effects for manipulated facial expression on felt aggressiveness, and Lanzetta et al. showed similar effects on pain. The facial feedback theorists, however, cannot explain the results of Schachter and Singer's experiment (but see comments by Izard, 1977, chapter 2). In addition, the Laird study did not contain the control group necessary to determine whether the appropriate expression increases the response to a stimulus or the inappropriate expression inhibits the response (or both). Laird also used self-report measures in a within-

[2] Since the physiological measures in Schachter and Singer were extremely crude, we cannot be entirely confident that the physiological patterns were identical. It is quite possible that the situational cues modified the physiological response.

subjects design, leaving open the possibility that demand characteristics were responsible for the results. Lanzetta et al. (1976) also used a within-subjects design, but their inclusion of a galvanic skin response (GSR) measure makes an account in terms of demand characteristics less plausible. However, since pain is not typically included in theories of emotion, their findings may not generalize to the feeling states that are.

The best evidence for the hydraulic view comes from studies showing a negative correlation between facial expressiveness and measures of physiological arousal (Buck, Miller, & Caul, 1974; Buck, Savin, Miller, & Caul, 1972; Lanzetta & Kleck, 1970). This evidence tends to disconfirm the other theories. However, few of the studies cited in support for this view actually show the negative correlation expected to hold *within* a given individual. Instead, they find evidence that the most expressive people are not the most physiologically aroused; they do not find that the same individual is more expressive when he is less aroused. In addition, several studies (including Lanzetta et al., 1976) have found significant *positive* correlations.

Thus none of the evidence is decisive, and most of the questions about the roles and relative importance of the various components of emotional responding remain open. This study attempts to answer some of these questions by testing several predictions from the facial feedback hypothesis. What we are calling the "facial feedback hypothesis" obviously derives from the theories of Tomkins (1962), who was the first to claim that the emotions are primarily facial behaviors, and later Izard, who maintains that "awareness of facial activity or facial feedback is actually our awareness of the subjective experience of a specific emotion" (1977, p. 60). Nonetheless the general hypothesis we are testing here is not the same as that of either of these theorists. In the first place, both theories are comprehensive statements containing numerous propositions about the relationship of emotions to personality, motivation, communication, and each other. The facial feedback hypothesis involves just one of these propositions, albeit a central one.

In the second place, neither author is entirely static in defining the implications of his general statements about the importance of the face. Our experiment was designed to test (a) whether the appropriate facial expression is necessary for the subjective experience of the emotion, and (b) whether the voluntary assumption of an expression is sufficient to produce the experience. If facial expression is *necessary* for emotional experience, there should be no emotion unless the face responds. Even in the presence of emotional stimuli, without the appropriate emotional expression, no emotion should be felt. If the facial expression is *sufficient* for emotional experience, when the face responds, the emotion should follow. Even in the absence of emotional stimuli, an emotional facial expression should produce an emotional feeling. Weaker forms of the hypotheses predict that feedback from the face should have a significant main effect on the emotional experience, attenuating or intensifying it. These hypotheses are derived from some of the more strongly worded statements of Tomkins (1962) and Izard (1977), statements that are qualified in other parts of their work. Both theorists argue that adults may have learned to duplicate the effects of proprioceptive feedback by means of a reafferent loop from the subcortical centers directly to the cortex, rather than from the subcortical centers to the face to the cortex, so that actual movement of the face is not always *necessary*. Similarly, they have argued that voluntary movement of the facial muscles may not be *sufficient* to produce the corresponding emotion, because it does not create exactly the same proprioceptive cues as the involuntary movement created by a "real" emotional stimulus.

Although the theories allow for the possibility that neither the necessity nor the sufficiency hypothesis is true, we believe that these hypotheses are worth testing. In the first place, the practical, therapeutic implications of the theory are much greater if the facial muscles are actually involved in the experience. If the face were necessary for emotional experience, victims of accidents, disease, or surgery resulting in facial paralysis or sensory impairment would be expected to show corre-

sponding affective deficiencies, and additional therapeutic attention would be indicated. If the face were sufficient to influence the felt emotion, it would be useful to teach patients suffering from affective disorders how to control their facial expressions. In the second place, the qualifications render the theory much less testable. If the only influential facial expression is one that results from an involuntary natural response and if the facial muscles can be bypassed intracranially, the causal role of the face becomes inaccessible to any sort of definitive empirical test.

A final hypothesis tested by our research is one that *does* follow directly even from the weaker statements of Tomkins (1962) and Izard (1977), as well as from the stronger facial feedback hypothesis. It is simply the prediction that, in general, the relationship between the facial expression and the emotional experience should be monotonic and positive.

The three hypotheses of necessity, sufficiency, and monotonicity were tested in this study by a design in which facial expression was manipulated independently of emotional stimulation. The basic design included a replication across two emotions—fear and sadness; we observed facial, physiological, and self-report responses. We chose fear and sadness because we felt that it was important to demonstrate a distinction between negative emotions. The comparison of a single positive with a single negative emotion does not provide a very stringent test of the qualitative distinctions among emotions, and is particularly prone to demand characteristics and level-of-arousal artifacts.[3] Because it included measures of all three sets of responses, the study can also address additional questions about their interrelationships and thus can provide a basis for comparing all the theoretical positions.

Method

Overview

Believing that the experiment was a study of physiological responses to subliminal stimuli, subjects watched a sad, fear-arousing, or emotionally neutral film. Their heart rate, galvanic skin response, and respiration rate were recorded, and the placement of additional fake electrodes on their faces provided a rationale for asking them to hold their facial muscles in a constant position during the film. These positions corresponded to a fearful expression, a sad expression, or a grimace unrelated to any emotion. A final group of subjects watched one of the three films but received no facial instructions. During the film the subjects' faces were videotaped, and as soon as it was over the subjects rated their emotional experience. The design was thus a 3×4 factorial with three films (fear, sad, and neutral) and four facial expressions (fear, sad, neutral, no instructions).

Subjects

The subjects were 128 undergraduates, 85 of whom received both credit (in partial fulfillment of introductory course requirements) and $2.00. The remaining 43 subjects received $3.00. Five subjects were not included in the analyses: 2 left the experiment when the content of the film was described to them, 1 stopped the film in the middle, and 2 others were lost because of equipment problems.

Procedure

There were two experimenters in the study. The first was blind to the subject's facial instruction condition. This experimenter (E_1) told the subject the basic cover story: the experiment concerned physiological indices of subliminal perception—heart rate, skin conductance, respiration rate, "the orienting reflex," and "subvocal speech"; all of these responses would be recorded on a polygraph, and the two that involved small movements of the eyes and lips would also be recorded on videotape. The subliminal stimuli would be single frames spliced into a film. E_1 then explained that certain parts of the procedure might cause some discomfort: (a) to prevent the subject from concentrating too hard on finding the subliminal images, the film was intended to be distracting, and might be upsetting; (b) since normal muscle movements could distort some of the physiological measures, the subject might be required to hold certain muscles in a somewhat uncomfortable position during the film; (c) since observers would later score the videotapes for the orienting reflex and subvocal speech response, absolutely complete anonymity could not be guaranteed. After explaining how the subject would be "hooked up" to the polygraph, E_1 described the content of the film and obtained the subject's formal consent.

---

[3] We considered a comparison between fear and anger, in an attempt to include a replication of Ax (1955). We had to abandon this plan for the interesting reason that we could find no film that consistently elicited anger more than other emotions in all subjects.

E_1 then left and sent the second experimenter (E_2) into the room. E_2 had been out of earshot and so was unaware of the subject's film condition.

E_2 placed the electrodes on the subject (electrocardiograph [EKG] electrodes on the wrists, a respiration thermistor[4] on the nostril, GSR electrodes on the middle finger, bogus electromyograph [EMG] electrodes on the face), explaining how they worked and reinforcing the rationale of the cover story. After the electrodes had been placed, E_2 told the subject to keep his or her arms still, and gave the instructions for holding the face in the position that would facilitate recording the facial responses. When E_2 was satisfied with the subject's facial pose, he left the subject alone for a baseline period with instructions to relax.

The baseline period lasted until the subject's physiological responses had appeared stable for at least 1 minute. Then E_2 began videotaping the subject's face and repeated the facial instructions (in a shorter form). When the facial expression was approximately right, E_2 told the subject to hold the position during the film; he then turned the projector on and immediately left the room. As soon as the film was over (E_1 watched through a one-way mirror for the end of the film), E_2 returned and administered a questionnaire containing the self-report emotion items, along with filler items consistent with the cover story.

E_1 debriefed the subjects. Although several subjects expressed confusion about the complex cover story, no one guessed that facial expression was the variable of interest, nor that his or her expression had been an emotional one.

Two male undergraduates took the E_1 role; one male graduate student took the E_2 role.

Independent Variables

Film. We pretested eight films on a group of 50 undergraduates, and selected three because they elicited high agreement across subjects on a single dominant emotion, with low ratings for all other emotions. Subjects rated each of five emotions on two 9-point scales (0–8) for each film. The ratings are the sums of the two scale scores. The *fear* film reliably elicited fear ($M = 5.5$); lesser degrees of pain, disgust, and interest; and relatively low sadness ($M = 2.4$). It concerns two accidents in an industrial shop. The *sad* film traces the reactions of a small boy to his brief stay in an orphanage while his mother is in the hospital. The sad film reliably elicited sadness ($M = 3.6$) and interest ($M = 3.4$) from pretest subjects, and low fear ($M = 0.75$). The neutral film depicts a flower show in the botanical gardens of Golden Gate Park. It was seen as slightly pleasant ($M = 2.8$) and interesting ($M = 2.1$) and not at all sad ($M = 0.20$) or frightening ($M = 0.02$). Each film lasted for 2 minutes.

Facial instructions. The facial instructions were derived from the work of Tomkins (1962), Izard (1971), Ekman and Friesen (1975), and the instructions used by the second author in developing prototype photographs for the Facial Affect Scoring Technique (Ekman, Friesen, & Tomkins, 1971). In practice, the instructions varied somewhat depending on how easily the subject adopted the desired position. For the subjects in the *fear face* condition, the instructions typically ran:

> There are three sets of muscles around the eyes that can distort the measurement of the orienting reflex. We want you to contract all three of them. The first is the muscle between the eyebrows, the corrugator. Contract that muscle by pulling the two eyebrows together, toward each other in the middle. The second is the muscle in the forehead, the frontalis. Contract the frontalis by raising your eyebrows. The last muscle is the one which controls the eyelids. Contract that one by opening your eyes up wide. There is only one set of muscles you'll have to contract in your mouth. First, part your lips slightly; it will be easier. The muscles here [points below corners of mouth] are the triangularis muscles. Contract them by pulling the corners of your mouth down and back. If you're doing it right, you should feel your neck get tense.

For the *sad face* subjects, the instructions were similar, although the muscles differed: the corrugator was contracted (brows drawn together), frontalis contracted (*inner corner* of the brows raised), eyelids relaxed, mentalis contracted (lower lip pushed up and out slightly), and quadratus muscles contracted (corners of lips pulled down). The *nonemotional face* subjects were instructed to close one eye, purse their lips, and puff out their cheeks. *Unmanipulated face* subjects were told to ignore the facial electrodes and to act "naturally," as we were "interested in determining whether the orienting reflex and subvocal speech responses can be detected against a background of normal facial movements." For all subjects, electrodes were placed on the chin and below one eye (for subjects in the nonemotional face condition, this bogus electrode was placed below the eye they were supposed to close).

Dependent Variables

Self-reported emotion. Fear was measured on two 9-point scales labeled "scared" and "afraid"; the scales ranged from "not at all" (0) to "very strongly" (8). These two scales were highly related ($r = .87$). Sadness was also measured on two 9-point scales; these were labeled "sad" and "unhappy" ($r = .71$). As in the pretests, the overall emotion score is the sum of the two scales.

Facial expressions. Two trained raters blind to the subject's conditions scored videotapes on the emo-

---

[4] Respiration rate was recorded as a control for certain heart rate artifacts. These corrections proved unnecessary. The results for respiration rate were not analyzed.

tional content of the subject's facial expressions. For each subject, the raters judged how sad, unhappy, scared, and afraid the subject looked. (The scales for these judgments were identical to those used by the subjects in judging their own emotions; they were, thus, 9-point scales ranging from "not at all" to "very strongly.") The facial sadness measure is the sum of the two raters' judgments for "sad" and "unhappy"; similarly, the facial fear rating is the sum of the two ratings of "scared" and "afraid."

Physiological indices. Physiological responses were monitored by a Narco-Bio Desk Model Physiograph. EKG electrodes were attached to the subjects' wrists with a ground electrode on the ankle. A cardiotachometer averaged the beat-to-beat interval over five beats and recorded the heart rate in beats per minute. The skin resistance was monitored by passing a small direct current through two plate electrodes attached to the top and bottom of the subject's middle finger.

Artificiality. Our efforts to keep the experimenters blind to the subject's condition, to prevent the subjects from guessing the hypotheses, and to collect three different kinds of data, although successful, resulted in a situation that was complicated and unusual and may recall the futile efforts of early researchers to obtain photographs of "true emotions" in the laboratory (e.g., Landis, 1924). Although emotional experience may have been attenuated in our setting, there is no evidence that this was the case. First, the self-reported emotional reactions to the films were at least as high as those obtained in pretesting; second, several subjects spontaneously commented on their emotional arousal, and one stopped the projector because the film was too upsetting; third, there were no false alarms in the reporting of subliminal stimuli, as might be expected if the task demands distracted subjects from the arousing properties of the films; and finally, unlike the early research, our emotional stimuli produced significant differences on the dependent variables.

Results [5]

Facial Expression

The judgments of facial expression appear to be reliable across raters: for the two-item sadness index, the two raters' judgments correlated .76 ($p < .001$); for the fear index, the two raters correlated at .81. For the remaining analyses, ratings were summed over the two judges.

The facial instructions had the expected large effect on the ratings of facial expression. On the average, subjects given the sad facial instructions were rated as more than 15 points sadder (on a 32-point scale) than the subjects given any of the other three facial instructions, $F(3, 3) = 153.1$, $p < .01$. Subjects given the fear face instructions averaged 13 points higher on rated facial fear, $F(3, 3) = 327.1$, $p < .01$. The facial instructions thus seemed to have succeeded.

There is also some indication that the film affected ratings of facial expression. Subjects watching the fear film looked more fearful ($M = 8.2$) than those watching the sad (4.4) or neutral (5.4) films, $F(2, 2) = 116.7$, $p < .01$. There was no corresponding effect for rated facial sadness. This effect provides some evidence for the validity of the judges' ratings (since the film might have been expected to affect facial expression in the obtained direction) and of the success of the films in creating real emotions but also indicates that the facial instructions manipulation was not wholly successful. Apparently subjects could not consistently maintain their instructed expression when confronted with the strong stimuli of the film. Though reliable, the effect of the film is small, particularly when compared with the effect for facial instructions.

There were no interactions nor main effects for experimenter on rated facial expression.

---

[5] The cell sizes in this study are unequal. While the differences are small, they may in part reflect the experimental variables of interest; the film, for example, may have affected subject attrition slightly (two fear film subjects, one sad film subject, and no neutral film subjects refused to participate after learning about the film they would see). Under these circumstances, weighted means analysis seemed most advisable (Winer, 1962, p. 222). Partly because the inequalities are so small, unweighted analyses yield identical conclusions.

The film and face variables were treated as fixed factors and experimenter as a random factor. Thus main effects for the film and facial instructions were tested against their interaction with the experimenter factor. Error terms based on pooling these interaction terms with the within-group sum of squares (Winer, 1962, pp. 202–207) do not alter the conclusions except where reported. The pooling procedure is used whenever permissible for planned and a posteriori comparisons, because of the handicap of 1 and 1 degrees of freedom. Small variations in the degrees of freedom in these analyses reflect missing data and the specific terms that could be included in the pooled error term.

Self-Reported Emotion

As Tables 1 and 2 show, the film had substantial effects on the subjects' ratings of their own emotions: for fear, $F(2, 2) = 29.5$, $p < .05$; for sadness, $F(2, 2) = 42.1$, $p < .05$. A priori contrasts indicated that subjects who watched the fear film were more frightened than subjects who watched the other films, $F(1, 106) = 17.9$, $p < .01$; subjects who saw the sad film were sadder, $F(1, 103) = 77.1$, $p < .01$. Each contrast accounts for more than 90% of the variance among the means for the three film conditions. (See Footnote 5 for an explanation of the degrees of freedom).

An examination of the difference between fear (or sadness) and the mean of all other emotion ratings confirms this analysis. Compared to subjects who watched the sad and neutral films, fear film subjects felt *predominantly* fear. For subjects who watched the fear film, the self-rated fear was 2.65 points higher than the average self-rating of all the other emotions; for sad film subjects self-rated fear was 1.06 points *lower* than the average across the other emotions, and for neutral film subjects it was about the same—0.28 points lower, $F(2, 2) = 113.8$, $p < .01$. The overall analysis also shows an uninterpretable Face × E interaction. No other effects are significant. Compared to subjects who watched the fear and neutral films, sad film subjects felt *predominantly* sadness. Their self-rated sadness was 5.20 points higher than the average of all the other emotions; for fear film subjects self-rated sadness was about the same as the average of all other emotions (.06 points lower) and for neutral film subjects 1.42 points lower, $F(2, 2) = 20.5$, $p < .05$. No other effects were significant.

Table 1
Mean Self-Reported Fear

Film	Facial instructions: Fear	Sad	Nonemotional	Unmanipulated	*M*
Fear	6.0	7.5	7.8	4.6	6.5
Sad	3.3	3.2	3.9	3.9	3.6
Neutral	3.3	2.1	2.3	2.2	2.5

Note. Scale ranges from 0 to 16, with higher numbers indicating greater fear.

Table 2
Mean Self-Reported Sadness

Film	Facial instructions: Fear	Sad	Nonemotional	Unmanipulated	*M*
Fear	4.1	4.4	4.7	3.5	4.4
Sad	8.9	8.8	9.7	8.8	9.1
Neutral	0.9	2.6	1.9	1.4	1.6

Note. Scale ranges from 0 to 16, with higher numbers indicating greater sadness.

Both the necessity hypothesis (that facial responses are necessary for the felt emotion) and the sufficiency hypothesis (that facial responses are sufficient for felt emotion) of the facial feedback theory predict effects for facial instructions. There are, however, no significant main effects for facial expression instructions on either emotion, nor does facial instruction interact significantly with film.

One possible interpretation of the lack of effects for facial instructions is that the subjects were simply unable to maintain their facial expressions during the film. Part of the film effect, then, may reflect covariation of the facial expression with the film condition. Partialing out variation in felt emotion due to facial expression through analysis of covariance, however, fails to alter significantly the very substantial film effects. The effects of the film on self-reported emotion are thus not attributable to differences in facial expression across film conditions.

A weakened version of the sufficiency hypothesis might predict that, in the absence of strong situational cues, the facial expression may be sufficient to determine felt emotion. The neutral film subjects, by this argument, should show an effect for facial expression. This prediction receives very slight support: among those subjects who watched the neutral film, the sad face subjects are, on the average, slightly sadder than subjects in the other three facial instructions conditions; similarly, of the neutral film subjects, the fear face subjects report the most fear. Neither of these

Table 3
Means on Physiological Indices by Film and Facial Instructions Condition

Condition	Fall in HR	Rise in HR	Fall in GSR	No. GSRs
		Film		
Fear	7.4	21.3	71.0	14.4
Sad	7.7	16.4	67.1	11.0
Neutral	10.8	14.6	52.2	11.7
		Facial instructions		
Fear	8.4	17.0	43.8	12.6
Sad	8.8	17.5	60.2	10.2
Nonemotional	7.1	19.6	63.8	15.8
Unmanipulated	9.9	15.7	86.2	11.0

Note. HR = heart rate (change computed in beats per minute). GSR = galvanic skin response (change computed in thousands of ohms).

trends for the neutral film subjects, however, is statistically significant, either by a priori comparisons within the context of the analysis of variance or by Kruskal–Wallis one-way analyses of variance for ranked data.

Overall, the relationship between facial expression and reported emotion is slight. The correlation between the ratings of facial fear and self-reported fear is .01; between facial and self-reported sadness, it is .02. The strongly positive relationship between facial expression and self-reported emotion predicted by all the facial feedback theories does not seem to obtain.

Physiological Measures

Two coders scored the polygraph recordings of the physiological variables. Their agreement was substantial, correlations between them ranging from .96 to 1.00 (median r = .98). Indices were based on six variables: baseline heartrate, the average of the subject's heart rate 10 and 5 seconds prior to the end of the baseline period (each heart rate reading is itself an average based on five beat-to-beat intervals); baseline skin resistance, also an average of readings 10 and 5 seconds prior to the end of the baseline period; maximum heart rate during the film period; minimum heart rate during the film; number of skin responses (any fall exceeding 1,000 ohms prior to leveling off was scored as a response); and lowest skin resistance during the film. Both skin resistance measures are reported in thousands of ohms. The heart rate (HR) measures are in beats per minute. The relevant means for the physiological variables are given in Table 3.

Rise in heart rate. The largest rise in HR for each subject was calculated as the difference between maximum and baseline HR. The film had a significant effect on this index, $F(2, 2) = 36.4$, $p < .05$. A posteriori contrasts (Scheffé criterion, Winer, 1962, p. 88) indicate that subjects who watched the fear film showed the largest rises in heart rate; neutral and sad film subjects showed smaller rises and were similar on this index, $F(1, 105) = 11.00$, $p < .05$; the contrast accounts for 96% of the variation among the means of the film groups. None of the other main effects or interactions are statistically significant.

Fall in heart rate. By subtracting the lowest heart rate from the index of baseline heart rate, we can find the largest fall in heart rate. There is a nearly significant effect for the film on this variable, $F(2, 2) = 17.1$, $.10 > p > .05$. An a posteriori contrast is similarly marginal: neutral film subjects show the largest drop in heart rate; fear and sad subjects show similarly smaller drops, $F(1, 105) = 4.78$, $.10 > p > .05$; the contrast accounts for 99% of the variation. There is also an effect for the facial instructions variable, $F(3, 3) = 37.2$, $p < .05$. Subjects in the nonemotional face condition show the smallest drop in heart rate, subjects in the unmanipu-

lated face condition the largest. The interaction term used to test this effect for facial instruction is quite small ($F < 1$); with a pooled error term, the effect is no longer significant: $F(3, 105) < 1$, *ns*. None of the other effects is significant.

Fall in GSR. Subtracting the lowest skin resistance from the baseline index yields a measure of overall change in skin resistance. Facial instruction condition has an effect on this variable: Subjects in the unmanipulated facial condition showed the largest drop in skin resistance, the fear instructions subjects the smallest. As with the facial instructions effect on fall in heart rate, the statistical significance of this is probably overestimated by the use of the Face × E interaction term as the error term: $F(3, 3) = 44.4$, $p < .01$; a pooled error yields $F(3, 97) = 1.7$, *ns*. The other effects do not reach statistical significance.

Number of galvanic skin responses. Each time skin resistance fell by 1,000 ohms, it was scored as a response. The film variable had a significant effect of the number of GSRs: $F(2, 2) = 57.1$, $p < .01$. An a posteriori contrast is marginally significant: Subjects watching the fear film had more GSRs on the average than the sad and neutral film subjects, $F(1, 98) = 5.63$, $.10 > p > .05$; the contrast accounts for 95% of the variation.

Summary of physiological effects. Three of the four physiological variables showed significant film effects. For heart rate fall, sad and fear film subjects were similar, both being lower than neutral film subjects. For rise in heart rate and number of skin responses, the sad film subjects were closer to the neutral film subjects. There was no reliable effect for film on largest fall in skin resistance, although the pattern was similar to that for heart rate (sad and fear subjects were similar and both were different from neutral film subjects). This pattern of different physiological signs for different emotional stimuli also appears in Table 4. The pattern of correlations between physiological variables and self-reported emotion differs for sadness and fear.

Both fall in heart rate and fall in GSR show some evidence for facial instructions effects, although the statistical significance of the effects depends on the choice of the error term. For fall in HR, the nonemotional facial instructions subjects seem the most "aroused" (showing the smallest drop). This is in line with the hydraulic–cathartic view. It is the unmanipulated subjects, however, rather than the fear or sad face subjects, who show the least "arousal" (largest drop). Similarly, the fear face subjects show the smallest drop in skin resistance, again in line with the hydraulic–cathartic view; however, this time the unmanipulated rather than the nonemotional subjects show most arousal. Table 4 offers further evidence of the traditionally weak and somewhat inconsistent relationship between facial expression and physiological response.

Table 4
Correlations of Physiological Variables with Facial and Self-Report Measures

Item	Self-report		Facial expression	
	Fear	Sad	Fear	Sad
Fall in HR	−.05	−.10	.02	−.01
Rise in HR	.16*	−.05	.04	−.02
Fall in GSR	−.05	.03	.08	−.08
No. of GSRs	−.05	−.18*	−.02	−.14
Maximum HR	.19*	−.08	03	.02
Minimum HR	.16*	.00	.01	−.01
Lowest GSR	.06	.19*	−.07	−.06

Note. HR = heart rate (change measured in beats per minute). GSR = galvanic skin response (change measured in thousands of ohms).
* $p < .05$.

Discussion

The Facial Feedback Hypothesis

On the assumption that the facial instructions had their intended effect, the facial feedback hypothesis receives three major setbacks from the evidence of this study. First, adopting an emotional facial expression does not appear to be *sufficient* to produce the emotion. Even when there were no competing emotional stimuli from the film (i.e., for the neutral film subjects), manipulated facial expression did not produce significant differences in emotional responding. The trend for these subjects, insofar as there was a trend, was in the

direction predicted by the facial feedback hypothesis. This trend appears to replicate Laird's (1974) results: the differences he found were of about the same magnitude as those in our neutral film condition, and it is probably a safe assumption that his stimuli (still photographs) were less arousing than our fear and sadness films.

Second, adopting a nonemotional expression does not prevent emotional responding; thus, emotional expression does not seem *necessary* for emotional feelings. Similarly, correcting for changes in facial expression statistically by analysis of covariance does not remove the effect of the film. Although this technique may be biased in the direction of undercorrection, it is hard to see how any statistical method based on the correlation between facial expression and reported emotion could alter the film effect—the correlation is zero.

Finally, this lack of correlation constitutes especially damaging evidence against the theory. Examination of the scatter plots of facial and self-reported fear and of facial and self-reported sadness does not provide obvious support for any monotonic relationship between self-report and facial expression of emotion, let alone the linear relation measured by the correlation coefficient. Thus, even a threshold version of the facial feedback hypothesis seems untenable. Lanzetta, Cartwright-Smith, and Kleck's (1976) finding of an effect of facial expression on feelings of pain does not seem to extend to feelings of fear or sadness.

Even if the facial manipulation were *unsuccessful,* the facial feedback hypothesis would be difficult to maintain. The absence of any correlation between rated expression and reported emotion might buttress an argument based on failure of the facial manipulation. The convergence of the facial instructions with raters' judgments could be explained away: raters might have recognized the intended expression even though subjects' faces were poor reflections of the canonical fear or sad expression. Granting both of these arguments, we still must explain the absence of inhibiting effects for facial expression; even if the facial manipulation of fear, for example, were woefully inadequate to produce the canonical fear expression, it is difficult to believe that it didn't greatly interfere with the emergence of the sad expression, thus reducing felt sadness. Finally, the existence of the film effect, its independence of the facial expression, and its magnitude compared with that of any facial effect present difficulties for the facial feedback position. As to these relative magnitudes, our results are in complete agreement with those presented by Laird (1974).

The lack of any correlation between facial expression and reported emotion is damaging not only to the rather strong and unqualified version of the facial feedback hypothesis tested in this experiment but also to the more elaborated, qualified theories proposed by Tomkins (1962) and by Izard (1971, 1977). Even if there are reafferent loops and even if the proprioceptive feedback along voluntary and involuntary pathways is recognizably different, the theories ought to predict a generally positive correlation. The unmanipulated face condition is especially relevant here, since there were no instructions to introduce potentially confusing voluntary feedback. In these conditions, all facial expression was spontaneous, and the correlations between expression and reported emotion were still infinitesimal ($r = -.01$ for fear; $r = .07$ for sadness).[6]

Physiological Results

It is possible that self-reported emotion may reflect the subject's perception of the expected effect of the film. Such demand characteristics are also relevant to Laird's (1974) study and may account for the effects of the stimuli on self-reported emotion in both his study and ours. The effects of the film on the physiological variables cannot be so easily accounted for by demand characteristics.

---

[6] In general the subjects in the unmanipulated face condition showed little overt facial response. It is possible that covert facial expressions, unobserved by our raters, did correlate with self-report of emotion (cf. Schwartz, Fair, Salt, Mandel, & Klerman, 1976). Thus it is still possible that covert involuntary muscle activity has some causal influence, although the difficulties of separating this influence from the effect of the eliciting emotional stimuli are enormous.

Table 5
Mean Physiological Arousal for Nonemotional and Unmanipulated Face Subjects in Neutral Film Condition

Item	Nonemotional	Unmanipulated	t (18)	p
Number of GSRs	16.4	10.0	1.94	.07
Fall in GSR	68.6	58.5	1.53	*ns*
Rise in HR	18.0	13.4	1.53	*ns*
Fall in HR	6.8	12.6	−1.74	.10

Note. $n = 9$ in the nonemotional face condition; $n = 11$ in the unmanipulated face condition. GSR = galvanic skin response (change measured in thousands of ohms). HR = heart rate (change measured in beats per minute).

Subjects who watched the fear film showed generally greater "arousal" than subjects who watched the sad or neutral film. The pattern of rises and falls for subjects who watched the fear film is quite similar to the pattern reported by Ax (1953) for fearful subjects. For the heart rate variables, sad film subjects were intermediate between fear and neutral film subjects. However, sad film subjects showed even fewer GSRs than subjects who saw the neutral film. These data support the notion of different physiological patterns for different emotions. This position receives further support from correlations between physiological variables and self-reported emotion; again, sadness seems related to lower levels of arousal, fear to higher levels. These findings tend to render the demand-characteristics account relatively less plausible. Fear film subjects seem to show the physiological pattern for fear. These findings also tend to render suspect the theoretical utility of the nonspecific arousal concept. (Of course, the mere existence of physiologically distinct patterns does not guarantee that people use them, as the James–Lange theory asserts, as cues to their emotional state.)

Facial and Physiological Variables

The Freudian hydraulic model suggests that there are different channels for emotional expression; as one channel is used more, the others are used less in releasing emotional energy. We might expect, according to this theory, negative relations between measures of physiological arousal and facial expression. Manipulated facial expression did have some effect on physiological responding, although the statistical significance of the findings is dubious. For the two heart rate variables and the number of GSRs, nonemotional face subjects did, in line with the hydraulic model, show more physiological "arousal" than subjects who received the other facial instructions. The results for unmanipulated subjects, whose facial emotion was more than that of the nonemotional face subjects but less than that of subjects posed with a fearful or sad expression, create difficulties for the hydraulic view. In general, the unmanipulated face subjects showed the least arousal.[7]

On the whole, these results are in line with an effort or concentration hypothesis. The nonemotional facial position, which required subjects to close one eye and puff out their cheeks, was probably the most difficult position to maintain and required a great deal of concentration. The unmanipulated face, of course, required no special effort at all. That concentration on a task can produce physiological changes has been amply demonstrated (e.g., Lacey, 1950; Lacey, Kagan, Lacey, & Moss, 1963). This mechanism can also account for the individual differences reported by previous investigators (Lanzetta & Kleck, 1970; Buck, Savin, Miller, & Caul, 1972; Buck, Miller, & Caul, 1974): "natural" in-

[7] The exception is fall in skin resistance. Unmanipulated subjects had the highest skin resistance during the baseline period. They showed the largest drop during the film; despite this, their lowest skin resistance during the film still averaged higher than that of subjects in the other groups. Some of their large drop doubtless reflects regression artifacts.

hibitors concentrate on inhibiting their facial expressions; this concentration produces changes in GSR. The effects of facial instructions on physiological arousal are not entirely in line with the hydraulic model and are perhaps better explained by an effort or concentration mechanism.

This hypothesis is, however, both tentative and post hoc. Although some of the facial effects are significant, others are not. Comparing nonemotional and unmanipulated face subjects across all film conditions a posteriori, the only physiological measure that is significantly higher in the nonemotional facial conditions is the number of GSRs, $F(1, 98) = 9.97$, $p < .05$. It might be argued that the purest test of the effort hypotheses is in the neutral film condition, where effort is the major source of physiological arousal. Table 5 shows the means for the four physiological variables for the nonemotional and unmanipulated face subjects who watched the neutral film. Testing all four physiological variables together, these two groups did not differ significantly, Hotelling's $T^2(4, 15) = 9.9$, $p < .25$. Although all the means differ in the direction consistent with an effort hypothesis, they do not reach conventional levels of significance.

Summary

In an area where counterintuitive theories and puzzling results seem the rule, our results seem to support a common sense theory. Emotional stimuli such as our films affect subjective experience, facial expressions, and physiological processes associated with an emotion. The effect of the stimuli does not, as the facial feedback hypothesis predicts, depend on the facial response. Nor, as the nonspecific arousal theorists claim, are the physiological effects the same for all emotions (although people may not pay any attention to the differences). Finally, covering up an emotion facially may increase physiological responding, but this increase does not appear to result from the emotion's having to "come out somewhere else" (as the hydraulic view would have). Instead, it seems plausible that the concentration required to repress the outward expression of an emotion has an effect on physiological response. Besides supporting the common sense view, these results also support a general self-perception hypothesis. A variety of cues—facial, physiological, situational—may enter into the subjective experience of an emotion. Our results suggest that the situational cues receive the most weight.

Deindividuation and Valence of Cues: Effects on Prosocial and Antisocial Behavior

Robert D. Johnson
Arkansas State University

Leslie L. Downing
Union College

Deindividuation has been shown to relate to increases in antisocial behavior. Typical manipulations, however, have confounded deindividuation with the presence of negatively valenced cues, such cues being inherent in the costumes or situations used to produce deindividuation. The present study manipulated deindividuation and valence of costume cues in a 2 × 2 factorial design. Zimbardo's theory of deindividuation suggests that deindividuation should disinhibit antisocial behavior, independent of cue valence, and should reduce any influence due to cues. Gergen, however, suggests that cues may have increasing influence, given deindividuation, and that deindividuation may increase prosocial behavior, given positive cues, and increase antisocial behavior, given negative cues. Results supported Gergen's position. Given options to increase or decrease shock level received by a stranger, no main effect was found for deindividuation. There was a main effect for costume cues, and an interaction of cues with deindividuation, with deindividuation facilitating a significant increase in prosocial responses in the presence of positive cues and a nonsignificant increase in antisocial responses in the presence of negative cues. Also cues interacted with trial blocks, prosocial behavior increasing with positive cues and antisocial behavior increasing with negative cues over trial blocks.

The construct deindividuation was first systematically investigated by Festinger, Pepitone, and Newcomb (1952). In their view, one consequence of an individual's involvement and identification with a group is a reduction of individual responsibility for individual behavior. They believed that deindividuation was a phenomenon on which groups would differ and that degree of deindividuation in a group could be indexed by the rate of failure of individuals to identify correctly the group members who had contributed different behaviors. It was expected that previously inhibited behaviors (i.e., saying negative things about one's parents) would be disinhibited as a result of deindividuation. As predicted, groups scoring highest on deindividuation did say more negative things about their parents. This was, however, a correlational study in which the direction of causality between deindividuation and disinhibition is unclear. Later studies (Singer, Brush, & Lublin, 1965; Zimbardo, 1970) using lab coats and hoods to obscure the identifiability of individuals, have shown that such a manipulation increases disinhibition of socially undesirable behaviors (i.e., speaking obscene words and administering electrical shock to another person).

Theoretical Issues

Exactly which behaviors will be disinhibited in a given situation is not yet clear. Nor is it clear how situational cues affect the type or amount of disinhibition that occurs. Two major positions on these issues have been advanced.

This article is based upon data submitted by the first author in partial fulfillment of requirements for the PhD degree at the University of Georgia, 1975. The second author was dissertation advisor. We thank Abe Tesser, Sid Rosen, Dick Endsley, and Dave Shaffer for their contributions to the project.

Portions of this article were presented at the 83rd Annual Convention of the American Psychological Association, 1975.

Zimbardo's view. In Zimbardo's theory of deindividuation (1970), anonymity, along with other input variables, produces a state of the organism, *deindividuation*, that in turn produces a general disinhibition of previously inhibited behavior. Negative comments about parents, college women's use of obscene words, and subjecting others to pain are all behaviors inhibited by prior experience, possibly by expectation of punishment. Deindividuation disinhibits such behaviors by means of a general weakening of inhibitory mechanisms. Which behaviors will be disinhibited depends upon which ones have been inhibited. Inhibited behaviors, once initiated, will tend to increase in frequency and intensity because they are intrinsically reinforcing. According to this theory, because the real source of the behavior is its intrinsically self-rewarding nature, deindividuation should lead to decreasing influence of external cues.

These hypotheses were subjected to an experimental test using what is perhaps the best-known deindividuation paradigm (Zimbardo, 1970). Groups of subjects were individuated (with identifying name tags) or deindividuated (with lab coats and hoods obscuring their identity) and were then given a sanctioned opportunity to administer electrical shocks to another person. Zimbardo has interpreted the increased duration of shocks given by deindividuated subjects to be a result of the deindividuating experience disinhibiting aggressive behavior.

As predicted, individuated subjects decreased shock over trials for a "nice" target person and increased shock for an "obnoxious" target, whereas deindividuated subjects increased shock for both targets. Also, shock duration and negativity of ratings of the target person were significantly correlated for individuated subjects, $r = .67$, but not for deindividuated subjects, $r = .10$. Contrary to prediction, however, the deindividuated subjects' average shock duration was higher for the "obnoxious" than for the "nice" target, whereas during the first half of the trials, individuated subjects actually shocked the "nice" target more than the "obnoxious" one. Deindividuated subjects thus seemed at least initially more "appropriately" responsive to target characteristics than were individuated subjects. Thus evidence for Zimbardo's prediction of reduced influence of situational cues, given deindividuation, is at best equivocal.

Gergen's view. The prediction that antisocial behavior is most likely to be disinhibited by deindividuation was questioned by Gergen, Gergen, and Barton (1973). In their study, darkness- and anonymity-induced deindividuation led not to increased aggression but to increases in touching, caressing, and other affectionate behaviors. These workers advanced the notion that either prosocial or antisocial behavior could be enhanced by deindividuation, depending upon valence of situational cues. In this view, the darkness manipulation may have been more suggestive of intimacy than of aggression, hence anonymity-induced deindividuation increased the frequency of intimacy behaviors.

Experimental Confounds

A more important question is whether the disinhibition observed in prior research was in fact due to deindividuation and not to some unintentionally manipulated variable. One such variable relates to the cue value of the deindividuating costumes, which may be reminiscent of Ku Klux Klan outfits or perhaps of some Halloween ghouls, either of which might be considered cues eliciting aggression (Berkowitz, 1974). It is noteworthy that even without differential identifiability, Berkowitz and his colleagues have demonstrated increased duration of shocks to a target person due to the presence of cues previously associated with aggression (Berkowitz, 1974). A similar line of reasoning could serve as an alternative explanation for differential levels of the use of profanity in the Singer et al. (1965) study. Old clothes (deindividuated condition) may have provided cues for lowered restraints against obscene language, whereas dressy clothes (individuated condition) may have provided cues to a number of learned associations of verbal restraint and propriety. Finally, the dark chamber used by Gergen et al. (1973) to deindividuate subjects

may have provided cues (e.g., darkness, the awareness of the presence of others through the sense of smell, the sounds of breathing, and the sense of touch, even if at first accidental) suggestive of intimacy and thus facilitating intimate behavior. In this study, however, a control condition indicated that darkness cues did not disinhibit intimacy if subjects were not anonymous.

The major question addressed by the present study is whether the direction of behavior change induced by nonidentifiability is influenced by the valence of situational cues. Given an influence of cues, Zimbardo's (1970) theory would predict that nonidentifiability will disinhibit aggressive behavior and that any effect of cues should be less than the effect for identifiable subjects. On the other hand, the reasoning of Gergen et al. (1973) predicts that nonidentifiability will lead to increases in antisocial behavior if antisocial cues are present and to increases in prosocial behavior if prosocial cues are present. A third possibility is that anonymity per se has no effect, but that prior demonstrations of anonymity effects actually resulted from confounded differences in situational cues.

Method

Subjects

Sixty female subjects were recruited from introductory psychology, sociology, and child development courses to participate in a study described as concerned with changes in group evaluations of a stranger. Most subjects were given extra credit in their course as an incentive to participate.

Procedure

Subjects were randomly assigned, 15 to each of four conditions, in a 2×2 factorial design that manipulated individuation (identifiable) versus deindividuation (nonidentifiable) and prosocial versus antisocial cues. Each subject was informed by phone, at the time she was recruited, that the experiment was to be run in groups of four, and that it was therefore very important for her to appear on time. Upon arrival, subjects were informed that each student had been asked to report to a different room in order to preclude interaction with others prior to the experiment. It was also explained that Polaroid pictures of the other group members would be used to establish the essential feeling of being part of a group and that disguises would be worn in the pictures to obscure individual difference characteristics that might be influential. In fact, although as many as four subjects were run in each session, each subject was treated completely independently of the others, and all subjects at any one time were in different treatment conditions. No subject had any contact with any other subject during the experimental session.

It was explained to each subject that the paid nonstudent male volunteer whom they would be evaluating was taking part in a verbal learning experiment and that it was important for them to become involved with the stranger. Involvement was to be established by their participation in selecting the level of shock that this person received for failure to respond correctly in the learning task. Subjects were instructed that it was an exploratory study on the effect of arousal on learning and that the experimenters did not know what effect different shock levels would have. Following each error the learner would be given a shock the base level of which could be increased or decreased by the responses of the subjects. The actual shock level received following an error would be the base level adjusted by the average adjustment selected by the four group members. Each subject would select high, moderate, or slight increases (+3, +2, +1) or decreases (−3, −2, −1) in the shock to be administered. It was explained that following each trial the subject would see on her console the shock selections of the other three subjects plus her own, that these would be averaged to determine the level of shock increase or decrease to be administered on that trial, and that no record would be kept of individual responses but only of the group average for each trial. Thus all subjects' responses, regardless of condition, were to be nonidentifiable to the experimenter and to any others who might see the data. The "learning task" ended when the subject had made 15 errors. The number of correct responses made prior to the 15th error was the measure of successful learning that subjects were to try to facilitate by their shock selections.

Cue manipulation. The costume manipulation of cues was produced by having each subject wear either a robe resembling those of the Ku Klux Klan or a nurse's uniform. The ostensible purpose of the costumes was to obscure individual differences. The nature of the specific costume given to each subject was presented as an accident of convenience (i.e., "I'm not much of a seamstress; this thing came out looking kind of Ku Klux Klannish," or "I was fortunate the hospital *recovery room* let me borrow these nurses' gowns to use in the study.") A Polaroid picture was taken of each subject in her costume, and pictures of others in the group, in similar costumes, were attached to the subjects' consoles. Each subject was told that copies of her picture had been placed on the consoles of others in the group.

Deindividuation manipulation. In the individuation condition, consoles were labeled so that each subject could identify the shock level set by each person in the group and the person by whom it was set.

Also, large name tags were attached to the costumes of the individuals in the Polaroid pictures. In the deindividuation condition, pictures of others in costume were attached to subject consoles, but no name tags were worn, and subjects were provided with no means of identifying the person who made any given response.

To facilitate subjects' involvement with the target, they were allowed to see and hear the "learner" being interviewed. His behavior in the interview was designed to be obnoxious and distasteful to the subjects. A negative target was used in order to minimize the inhibitions against shocking another person, thus allowing for variability on this response dimension. In fact, subjects proved not to be too inhibited to use the shock increase option, yet the target was not so negative as to preclude use of the shock decrease option.

Following the interview, subjects filled out a preliminary evaluation of the confederate. Learning trials were then begun, errors being indicated by the lights on the subjects' consoles, signaling to them to select +3, +2, or +1 levels of increase or −1, −2, or −3 levels of decrease in intensity of the shock the confederate was to receive. After all subjects in the group had responded, feedback of the choices of others was displayed and shock was supposedly administered. Feedback was preprogrammed to average 0 across each of three blocks of trials. Following the learning task, subjects were asked to fill out a postexperimental questionnaire, after which they were probed for suspicion, debriefed, asked not to divulge the deceptions to others, and dismissed.

Results

Evaluation of the Stranger

Five bipolar scales for evaluating the stranger were administered immediately following the interview, prior to the learning task. The experimental conditions did not significantly differ from each other, the means for each condition being on the *insincere, dishonest, cold, phony,* and *unkind* side of the midpoint. It appears that the confederate was perceived to be obnoxious, as planned, in all conditions.

Manipulation checks

Perception of cues. Four bipolar scales on the postexperimental questionnaire were used to assess subjects' perception of costume cues. As intended, the Ku Klux Klan costumes were rated as significantly more tough, harmful, unkind, and cold than were the nurses' costumes, $p < .01$, for each scale. Composite totals of responses to these four scales indicated that the Ku Klux Klan costumes were perceived as significantly more negative than the nurses' costumes, $F(1, 56) = 24.95$, $p < .01$. This difference reflects the negative ratings of the Ku Klux Klan costumes, $M = 5.59$, versus the slightly positive ratings of the nurses' costumes, $M = 3.71$ on a 1 (extremely compassionate) to 7 (extremely aggressive) scale.

Table 1
Mean Shock Selection as a Function of Cue and Deindividuation Conditions

Cue	Condition	
	Individuated	Deindividuated
Prosocial	$-.35_a$	-1.47_b
Antisocial	$.76_c$	$.95_c$

Note. Possible range of scores was from −3 (the prosocial choice of maximally reducing shock level) to +3 (the antisocial choice of maximally increasing shock level). Means without a common subscript were significantly different from each other ($p < .01$).

Perceived sense of deindividuation. As expected, deindividuated subjects, compared to individuated subjects, indicated on the postexperimental questionnaire that it would be more difficult to identify shock selections of other individuals in their group, $F(1, 56) = 15.84$, $p < .01$, and that it would be more difficult to distinguish members of their group from nongroup members following the experiment, $F(1, 56) = 19.55$, $p < .01$. These measures suggest that in fact deindividuation was manipulated as intended.

Shock Selections

The primary dependent variable, shock selection, was analyzed by a $2 \times 2 \times 3$ analysis of variance, individuation versus deindividuation, and prosocial versus antisocial cues between subjects and trial blocks within subjects. This analysis revealed a significant main effect for cues, $F(1, 56) < 46.28$, $p = .01$, with shock decrease the mean response for prosocial cues and shock increase the mean response for antisocial cues. The main effect for individuation versus deindividuation was

not significant, $F(1, 56) = 2.92$, but there was a significant Cues × Deindividuation interaction, $F(1, 56) = 8.21$, $p < .01$. The interaction (see Table 1) is a result of an increasing effect of cues on behavior in deindividuated versus individuated conditions.

A Newman-Keuls test revealed that each condition was significantly different from each other condition, each at the $p < .01$ level, except the simple effect of deindividuation within antisocial cues. This comparison is essentially a conceptual replication of Zimbardo (1970). It was directionally consistent with that effect but only achieved $p < .15$ even by a one-tailed simple t test.

No significant main effect occurred for trial blocks, $F(2, 112) = 1.31$, or for the interaction of trial blocks with deindividuation, $F(2, 112) = 1.85$. There was, however, a significant Trial Blocks × Cues interaction, $F(2, 112) = 19.78$, $p < .01$, resulting from the tendency for shock levels to increase in the antisocial cues condition and to decrease in the prosocial cues condition, from the first to the second of three blocks.

Discussion

The experimental manipulations appear to have been effective. The prosocial costumes, though closer to neutral than had been intended, were rated as significantly less negative than the antisocial costumes. The manipulation of deindividuation was assessed by self-reports of ability to identify behaviors of specific group members (cf. Festinger et al., 1952) and perceived anonymity of group members (cf. Zimbardo, 1970). Both measures demonstrated that deindividuation was manipulated as intended.

Of primary interest in this research were the effects of cues and of deindividuation on shock selection. In the presence of Ku Klux Klan costume cues, subjects were likely to increase shock levels, whereas in the presence of prosocial cues, subjects were likely to decrease shock levels. This finding by itself suggests alternative interpretations of the Singer et al. (1965) study and the Zimbardo (1970) study presented in this paper's introduction. In those studies costume cues were completely confounded with the manipulations of deindividuation. It is entirely possible that the increased antisocial behavior observed in those studies (i.e., frequency of obscene words and duration of electrical shocks) was a function of the costume cue manipulation alone and depended less on anonymity than has been widely believed.

In contrast to the previous research, the present study allows us to look at the effects of deindividuation independent of costume cues. According to Zimbardo, (a) deindividuation should have resulted in more aggressive, antisocial behavior for both costume variations, and (b) any effect of cues should have been attenuated as a function of deindividuation. According to Gergen et al. (1973), however, cues should interact with deindividuation, deindividuation leading to more antisocial behavior in the presence of antisocial cues and to more prosocial behavior in the presence of prosocial cues. The interaction obtained in the present study (see Table 1) is consistent with Gergen's position.

Theoretical Implications

Antecedents of deindividuation. Conceptually, most theorists (cf. Zimbardo, 1970) have viewed deindividuation as a state of the organism that can be induced by a variety of input variables, including but not limited to anonymity. Experimentally, however, deindividuation has nearly always been manipulated by varying some aspect of identifiability. This is true of the research discussed in the introduction and is true of the present research. More recently (cf. Diener, in press), deindividuation has been manipulated by means of complexes of input variables including a sense of group unity, group cohesiveness, group responsibility, and even kinesthetic feedback from physical activity. These inputs may in fact induce a sense of anonymity, but very likely they have additional influences beyond those related to identifiability.

The state of deindividuation. Confirmation of the relationship between anonymity and disinhibition is not sufficient to support

the construct of deindividuation as a mediating state of the organism, and attempts to validate the construct have been largely unsupportive (Diener et al., 1975; Diener, in press). Anonymity-induced disinhibition may not require a reduction in the subjective sense of individuation but in many instances could reflect a simple reduction in perceived negative sanctions, hence a disinhibition of behavior previously suppressed by such sanctions. Possibly environmental cues, like demand characteristics, influence the subjects' interpretation of the types of prior sanction that have been lifted.

Individuation and objective self-awareness. Conceptually, a strong parallel seems to exist between Zimbardo's (1970) constructs of individuation versus deindividuation and the Duval and Wickland (1972) constructs of objective versus subjective self-awareness. For example, both individuation and objective self-awareness imply focusing of attention inward, toward the self. Recent research has shown that a typical manipulation of objective self-awareness does in fact lead to an increased sense of individuation (Ickes, Layden, & Barnes, 1978). Also, Diener (in press) has demonstrated a reduction in self-awareness resulting from a broad-based group involvement manipulation of deindividuation but has found this to be not equivalent to lack of self-awareness induced in a nonsocial way. This does not imply that anonymity will not yield a lack of self-awareness comparable to that of typical objective self-awareness manipulations, for Diener's manipulations of deindividuation included much more than anonymity.

Objective self-awareness and situational cues. The state of objective self-awareness has been shown to increase the influence of internalized standards for correct or appropriate behavior (Carver, 1975; Scheier, Fenigstein, & Buss, 1974). Conversely, one might expect objective self-awareness to reduce the influence of external, situational cues. If anonymity-induced deindividuation is comparable to reduced objective self-awareness, the anonymity should increase the relative influence of external cues. Basically, we are suggesting that reduced objective self-awareness, anonymity-induced deindividuation, and probably group involvement-induced deindividuation all lead to an outwardly focused attention with increased salience of and influence due to concurrent situational factors such as the cue manipulation in the present study. Also, individuation and objective self-awareness should focus attention inward, increasing the salience of and influence due to internalized standards for behavior (cf. Carver, 1975).

Under some circumstances, internalized standards may themselves be altered by concurrent stimulus information (cf. Carver, 1974), in which case the influence of such external stimuli may be increased by objective self-awareness. Consequently, statements as to whether anonymity will lead to increased or decreased influence of external cues may need to be qualified to take into account how or whether those cues affect a change in internalized standards for behavior.

Social and Emotional Messages of Smiling: An Ethological Approach

Robert E. Kraut and Robert E. Johnston
Cornell University

Did smiling evolve as an expression of happiness, friendliness, or both? Naturalistic observation at a bowling alley ($N = 1,793$ balls) shows that bowlers often smile when socially engaged, looking at and talking to others, but not necessarily after scoring a spare or a strike. In a second study, bowlers ($N = 166$ balls) rarely smiled while facing the pins but often smiled when facing their friends. At a hockey game, fans ($N = 3,726$ faces) smiled both when they were socially involved and after events favorable to their team. Pedestrians ($N = 663$) were much more likely to smile when talking but only slightly more likely to smile in response to nice weather than to unpleasant weather. These four studies suggest a strong and robust association of smiling with a social motivation and an erratic association with emotional experience.

Everyday experience suggests that smiling is one of the most common nonverbal signals used in communication among humans. Despite this, and despite more than 100 years of research on facial expressions, we still know relatively little about the causation of smiling and its social functions. In this article we attempt to provide evidence about the causation of smiling in social settings and to raise some neglected questions about the analysis of facial expressions in general.

Research and thought on the facial expression of emotion has had a checkered history since the publication of Darwin's *The Expression of the Emotions in Man and Animals* in 1872, as has been documented by a number of excellent reviews (Ekman, 1973; Ekman, Friesen, & Ellsworth, 1972; Izard, 1971), but recently several of the perennial questions in this field have been settled. In a variety of studies researchers have shown that people can consensually and accurately recognize at least six emotional expressions from pictures of faces (e.g., Ekman, 1972; Ekman et al., 1972; Tomkins & McCarter, 1964) and that these abilities seem to be universal among humans (Eibl-Eibesfeldt, 1972 and 1973; Ekman, 1973; Izard, 1971; Vinacke, 1949; Vinacke & Fong, 1955). Ekman (1972) has proposed a general model for the factors influencing facial expression that we take as representative of this "emotional expression approach" to facial expressions, and we explicate this model in more detail below for the particular case of smiling. Tomkins' (1962) and Izard's (1971) positions emphasize the influence of facial expressions on emotional experience more than Ekman's approach does but are otherwise similar.

The Emotional Expression Approach: Smiling as the Expression of Happiness

According to the emotional expression view, a smile is the major component of a facial display associated with and caused by feelings

This research was supported in part by National Institutes of Health Grant MH 30041 to Robert Kraut and National Science Foundation Grant BNS 76-18681 to Robert Johnston. Peter Goldenthal, Virginia Engelhard, David Eaton, Celia Littauer, Cynthia Morgan, Sherrie Zweig, and Barbara Peterson provided valuable discussion in early stages of the research and helped collect data. Scott Hamilton, manager of Ide's Bowling Lanes in Ithaca, New York, was both generous and patient about our research efforts.

of happiness or joy. Anything that makes a person feel good or happy should produce smiling unless the individual wants to mask or inhibit this display. Laughing is considered to be the expression of either more intense happiness (Darwin, 1872/1965) or a particular type of happiness (Ekman & Friesen, 1975). Cultural and individual differences influence smiling both by determining the interpretation of events, which affects the cause of happiness, and by shaping display rules, which determine when it is socially appropriate to smile. But such differences do not alter people's innate and universal tendency to smile when they are happy. Thus, when a smile does occur, the message is usually happiness (Ekman & Friesen, 1975), although this may be a false message if the sender is masking another emotion with a smile or if the sender is simulating happiness for some other reason.

It is important to note that although workers in this tradition have emphasized the importance of facial expression in communication and social behavior, they have rarely studied such communication in natural social settings by studying the causes and consequences of smiling; rather, they have focused on the recognition and verbal labeling of emotions in facial expressions, generally in still photographs.

Ethological Studies: Smiling Indicates Friendliness

A different paradigm has of necessity been used by ethologists studying nonhuman primates. These workers have used naturalistic observation as a research tool and have drawn many of their hypotheses about humans from comparisons of humans with other primates; they have concentrated on the proximate causes of smiling, its consequences for the immediate interaction, and its evolutionary functions.

Many nonhuman primates have a submissive facial display, called a grimace, a grin, or a silent bared-teeth face. The display resembles the human smile, and in all species in which it occurs, it seems to have the function of deflecting hostile behavior of more dominant animals (Hooff, 1962). In a detailed study of chimpanzees, Hooff (1972, 1973) showed that in addition to averting attacks, variations of this display were used to maintain or increase affiliative behaviors between individuals. In some circumstances dominant animals used one variety of the bared-teeth face to reassure subordinates of their nonhostile, affiliative intent. Hooff hypothesized that the human smile is evolutionarily related to the chimpanzee's bared-teeth displays and serves the same functions of deflecting hostility and maintaining friendly contact. On the other hand, according to Hooff, laughter evolved independently and is related to the primate "play face."

If human smiling is a behavioral homologue of chimpanzee bared-teeth displays, one would expect smiling to occur most in face-to-face interaction, especially where friendly intent is problematic or where social bonds are being established or renewed. The smiler's motivation may be genuine friendliness or an intent to establish friendly relations. Researchers in this ethological tradition have not been concerned with the emotions or feelings experienced by those doing the smiling.

The two approaches outlined above are not necessarily incompatible, but they have talked past each other by using different methodologies on different species to ask different questions. The present article tries to compare predictions based on smiling as the expression of happiness with those based on smiling as an indication of friendliness, since the most straightforward extrapolations from each position do lead to different predictions about the causes of smiling in social settings. We asked about the motivational state of the smiler and the conditions under which smiling is produced, and we used naturalistic observation as our methodology. We chose public settings in which we could observe people's faces, in which the two theoretical orientations would predict that smiling would occur frequently, and in which we could distinguish the two theories. Thus, for a setting to be relevant to the emotional orientation, emotionally arousing and happiness-producing events had to be frequent. To be relevant to the social orientation, social interaction had to be frequent.

Study 1: Naturalistic Observations of Bowling

Watching bowlers is an excellent way to distinguish the social and emotional hypotheses about the causation of smiling. Observations of the progress of the game and the actions of friends and teammates provide evidence about external events that might cause smiles, and observations of the bowlers' behaviors as they are smiling provide evidence about their motivational states.

According to the emotional hypothesis, bowlers should smile whenever they feel happy, for example, immediately following a spare or strike. But according to the social hypothesis, smiling should occur during social interaction, and the score obtained should be irrelevant.

To some extent, the entire game of bowling is played in a social context. Bowlers generally play with several friends or teammates with whom they talk and drink between turns and who shout encouragement, taunts, and insults after the play (see White, 1955, for a lively description). Yet during the game, the extent to which bowlers are engaged in social interaction varies greatly from moment to moment. When bowlers are facing the pins, preparing to roll the ball and watching the outcome, social interaction is minimal. It increases when they turn to face friends and is greatest when they are engaged in face-to-face interactions in close proximity to them. The social hypothesis predicts that smiling should occur most during these bouts of more intense social involvement.

Method

The bowling alley in which we made observations had 36 lanes. The lanes were set up in pairs with a scoring table centered about 4.5 meters behind the foul line and a semicircular bench defining a pit for bowlers waiting their turn. Behind the pit and a guardrail was a gallery with small tables at which spectators and bowlers might sit, watch the game, and drink.

Although there were many variations, most bowlers followed a predictable sequence. They would arise from a seat in the pit, select a ball from the ball return located between the two lanes, approach and release the ball at the foul line, stand or back up while facing the pins to see the outcome of the roll, turn 180° to face the pit, and walk toward the pit. After turning from the pins, they might show a communicative display or engage in social behavior, and they would then go back to the ball return and start the second roll. At the end of the second roll, bowlers would return to their seats or leave the pit, occasionally talking to people on the way.

We made observations of bowlers who appeared to be at least 18 years old. Lanes to observe were arbitrarily chosen from among those with an open spectator table located about 7 meters behind the foul line. If no spectator tables were available, observers arbitrarily selected a lane and observed while leaning against a wall. An observer recorded behavior from all bowlers using a selected lane for a maximum of 20 rolls of the ball from all bowlers. At the end of 20 rolls, the observer moved to another arbitrarily chosen lane. Most bowlers were unaware that they were being observed by us. Those bowlers who asked were told that we were watching their technique and their score.

The observer recorded verbal and nonverbal data about bowlers from the time they turned to face the pit after bowling until they turned away to pick up the ball after the first roll or returned to their seat, left the pit, or turned away from the observer after the second roll. The mean length of an observation period for a sample of 120 rolls was 5.5 seconds. A pattern of body and facial behavior believed by the observer to have occurred simultaneously was recorded as a unit. If an element in the display changed or if the same pattern was held for what seemed a very long time to the observer, the observer recorded another unit.

Our observational study of bowlers was replicated three times, using slightly different lists of behaviors, different observers, and different recording techniques. Over all replications we observed 1,793 rolls of the ball, based on approximately 350 different bowlers. Observers were trained by watching and recording from videotapes of people bowling. In the first replication, observers were five students in a seminar on human ethology and the two authors. We were aware of the hypotheses of the study and recorded behaviors using a brief notational scheme with pencil and paper. In the second replication, two observers naive to the hypotheses of the study watched 550 rolls of the ball and recorded behaviors by speaking code names of the behaviors into portable tape recorders, pausing between behaviors in order to indicate unit boundaries. Using this technique, observers didn't have to remember behavioral sequences as long and didn't have to look away from the research subjects to record data; they were therefore able to record more behaviors and units per observational period.

In the third replication we videotaped 155 rolls of the ball and made detailed analyses of these tapes. Recordings were taken with bowlers' awareness and permission. We set up the lights and camera at the spectator table and pretended to film for 5 minutes prior to the actual filming to acclimate subjects to

the equipment. Two observers recorded data from these tapes. As soon as both eyes of the subject could be clearly seen, the observers stopped the tape, recorded behaviors, hand-turned the tape one quarter-turn, recorded behaviors, and repeated this sequence until the subject moved out of focus or turned so that only one eye could be seen. Using this method, data were recorded at approximately two-thirds-of-a-second intervals. After this stop motion analysis, the tapes were played at least once at normal speed to validate the behaviors recorded.

We did no reliability checks on the live recording. On the analysis of the videotaped sequences the two observers agreed on 97% of the behaviors that either recorded.

We recorded the following behaviors because prior research suggested that they might be communicative and because pretesting showed that they had occurred with sufficient frequency to allow meaningful statistical analyses:

Neutral face: blank expression; mouth relaxed; head straight forward; absence of all other coded behaviors except *talked to, groom,* and *good score.*

Closed smile: corners of the mouth turned up; lips together; teeth together.

Open smile: corners of mouth turned up; lips are parted to show teeth. In Replication 1 only, smiling was coded without distinguishing between closed- and open-mouth smiles.

Laugh: mouth open, corners of mouth sometimes turned up; laughter accompanying open mouth.

Tight lips: lips compressed tightly; mouth in straight line; teeth probably clenched.

Look: gaze fixed on another person.

Look down: gaze directed at floor.

Look away: head turned off body axis, gaze not directed at others in group.

Talk: vocalization by subject to another person.

Talked to: vocalization directed to the subject.

Groom: subject preening, scratching, or rubbing any part of his body or face.

Face cover: one or both hands covering facial features for several seconds. This was not recorded in Replication 2.

Head shake: a continuous horizontal movement of the head, usually repeated several times.

Ham: a nonspontaneous, exaggerated facial or body expression apparently intended to communicate; for example, "funny" faces, sticking out tongue, wrinkling nose, jumping up and down, dancing a "jig."

Positive exclamations: spontaneous and often exaggerated actions or words that the observer believed corresponded to a pleasant experience or one during which the individual felt pleasurably excited. For example, a leap and squeal of joy after a strike.

Negative exclamations: spontaneous and often exaggerated actions or words that the observer believed corresponded to an unpleasant experience. For example, swinging the fist across one's body, stamping one's foot, or swearing after missing the pins. Exclamations were more spontaneous, less exaggerated, and shorter, and appeared to be less intentially communicative than hamming, with which they might be confused.

Good Score: a strike or spare.

Sequential Analysis

In order to understand the causes of smiling, it is necessary to examine the events with which it is temporally associated. If smiling often followed an external event in the smiler's environment, it is possible and even likely that the event caused the smile. If smilers often performed other behaviors while smiling, it is likely that the motivation underlying the other behaviors is also underlying the smiling.

Whether we consider two events or behaviors temporally associated depends on the time unit we select; the meaning of *simultaneous* depends on temporal resolution. In Replication 1 we have considered two behaviors as temporally associated or co-occurring if the original observer thought that they had occurred simultaneously, that is, placed them in the same behavioral unit, or if the observer placed them in adjacent behavioral units. Replication 2, using tape recorded data collection, and Replication 3, using analysis of videotapes, had finer temporal resolution. Therefore, to make all data analyses comparable, we considered two behaviors as co-occurring if they occurred within 3 behavioral units of each other in Replication 2 and within 8 behavioral units of each other in Replication 3. This means that we considered two behaviors as temporally associated if they occurred within about 4 seconds of each other.

Because the frequency of co-occurrence is biased by the frequency of each behavior, Yules Q or gamma is the appropriate measure of association to use. We use this statistic rather than the more familiar phi correlation because we considered a positive or negative association between two behaviors as perfect if the more frequent behavior always or never occurred with the less frequent behavior (Blalock, 1972, pp. 298–299).[1]

---

[1] The formula for gamma in this research is as follows. Let A = the frequency of co-occurrence. T = total behavioral units; this is the total number of opportunities for co-occurrence. Ant = the frequency

Results

The data were stable and the co-occurrence of smiling with other behaviors is similar across the three replications. The mean Pearson correlation between columns in Table 1 is .80 ($p < .001$).

The social hypothesis leads us to expect that bowlers will smile when they are socially motivated independently of emotional experience. Table 1 provides evidence of this. Bowlers were more likely to smile when they were engaged in social contact, for example, when looking at their friends ($M\ \gamma = .71$), and less likely to smile when they were temporarily avoiding social contact for some reason and were looking at the ground or away from their friends ($M\ \gamma = -.56$). In addition, bowlers showed a tendency to smile more when they were talking to friends or being talked to by them ($M\ \gamma = .20$).

Smiling, especially open-mouth smiling, also occurred with playful behaviors; laughter ($M\ \gamma = .23$ over all smiles; $M\ \gamma = .80$ for open-mouth smiles), hamming ($M\ \gamma = .33$ for all smiles; $M\ \gamma = .47$ for open-mouth smiles), and face-covering ($M\ \gamma = .34$ for all smiles; $M\ \gamma = .93$ for open-mouth smiling). At the bowling alleys, open-mouth smiling occurred when bowlers were being socially playful. Since nonsocial playfulness rarely occurred in this setting, we cannot tell if the social or the playful motivation was a more important determinant of open-mouth smiling.

The happiness hypothesis leads us to expect that bowlers would smile more after playing well and bowling a good score, but this was not the case. The association between smiling and scoring a spare or strike was weak ($M\ \gamma = .13$). Of the 1,793 rolls for which we collected data, 448 were spares or strikes. Bowlers smiled 30% of the time after good scores and 23% otherwise. Other support for the happiness hypothesis is mixed. In general, smiling showed weak associations with the behaviors that we had identified as subtle indicators of negative affect and stronger associations with larger scale emotional displays. Thus, smiling had little association with the subtle cues of grooming and head shaking. Smiling had a substantial negative association with the tight-lip display, which our observations had led us to believe was an indicator of anger, frustration, and perhaps determination. It is a component in the traditional anger display (Ekman & Friesen, 1975). However, the negative association could have been partly caused by the physical difficulty a bowler would have smiling and lip pressing simultaneously (and the difficulty coders would have distinguishing two behaviors in the mouth region) as well as by the emotional incompatibility of smiling and lip pressing.

On the other hand, the spontaneous emotional displays we have termed positive and negative exclamations showed substantial associations with smiling. When bowlers were communicating surprise and glee, generally after getting a good score, they smiled ($M\ \gamma = .49$); when they swore and showed other signs of disappointment and anger, generally at not getting a good score, they failed to smile ($M\ \gamma = -.49$). Since smiling showed no association with score, which is the likely cause of bowlers' emotional experience, these data suggest that when bowlers were attempting to communicate their happiness through positive exclamations, they used smiles as part of the communication; when they were experiencing positive emotions but were not attempting to communicate them, however, smiling did not covary with other subtle behavioral indicators of their emotional state.

Several problems limit confidence in the conclusions one can draw from these co-occurrence data. As we have suggested above, the degree of temporal co-occurrence between behaviors may reflect as much their physical

---

of the antecedent behavior; this is the maximum number of times it could have co-occurred with a subsequent behavior. Sub = number of behavioral groupings (i.e., two behavioral units in Replication 1, three units in Replication 2, and eight units in Replication 3) in which a subsequent behavior occurred; this is the maximum number of times it could have co-occurred with an antecedent behavior. Then $B = Ant - A$; $C = Sub - A$; $D = T - A - B - C$; $\gamma = [(A \times D) - (B \times C)]/[(A \times D) + (B \times C)]$. Since the gamma based on Behavior X preceding Behavior Y is not necessarily the same as Y preceding X, we used the mean of these two measures in all our analyses.

Table 1
Temporal Associations (Gamma) of Smiling and Other Behaviors

Behavior	Replication 1	2		3		*M* all smiles[a]	*t*
	All smiles	Closed smile	Open smile	Closed smile	Open smile		
Neutral face	−77	−52	−88	−70	−93	−76	10.5
Closed smile	—	—	−19	—	05	−07	—

Head shake	−18	17	−07	12	15	04	.55
Positive exclamation	24	23	71	72	56	49	4.53
Negative exclamation	−65	−59	−40	−16	−64	−49	5.22
Good score	07	37	29	01	−09	13	1.50

Note. Decimal points have been omitted.
[a] In this table significance tests have not been performed on the individual gammas, since the units on which they are based were not independent of each other. They are based on 5,527 overlapping 4-second periods in which two behaviors could co-occur, spread over 1,793 rolls of the ball and over approximately 350 different bowlers. The *t* tests performed on the mean gammas are based on five observations and test whether smiling is associated with the other behaviors reliably over the different replications and types of smiles.

compatibility as their similarity in underlying motivation or external causation. For example, since smiling, laughing, talking, and compressing one's lips are all behaviors done by the mouth, their mutual co-occurrence is limited. Similarly, the neutral display, by definition, cannot co-occur with other behaviors. A second problem could be a result of observer errors. Faced with a rich and complex event, observers' errors tended to be omissions; our training procedures showed that observers were more likely to ignore behaviors that did occur than to record behaviors that did not occur. What might be termed a climax error may be characteristic of event sequences in which observers underreport low intensity forms of a behavior that gradually change to a climax form of the same or another behavior. For example, it is possible that smiling might be underreported in the sequences leading to laughter, hamming, and positive exclamations, while tight lips and grooming might be underreported in the sequences leading to negative exclamations.

A third problem is more conceptual. Our research strategy has been to infer the messages of smiling by examining other behaviors with which it occurs, that is, marker behaviors. Our beliefs about the significance of these other behaviors were based on the prior literature on nonverbal communication, on informal observation in our research setting, and on intuition. More systematic analysis of the patterns of co-occurrences among marker behaviors could provide direct evidence on the significance of marker behaviors and might provide deeper insight into the messages of smiling.

Principal Components Analysis

One partial solution to these problems is to analyze the similarities in co-occurrence that pairs of behaviors had with other behaviors

rather than analyzing only the temporal association between pairs. For example, if lip tightening and closed-mouth smiling were equivalent but alternative behaviors, an analysis of temporal association would show that they never co-occurred, but an analysis of their similarities in co-occurrence would show that they occurred in exactly the same contexts. Following Hooff's logic (1973), we started with the assumption that to the extent that a pair of behaviors occurred in the same contexts, that is, to the extent that they had similar co-occurrences with other behaviors, they also shared underlying motivations or external causes. The Pearson correlation between rows in a matrix of gamma scores (our measure of co-occurrence) is one measure of the extent to which the pair of behaviors represented by the rows had similar co-occurrences with each other behavior, including co-occurrences with themselves. Because the three replications of our basic study resulted in three estimates of the co-occurrences between each pair of behaviors, we took the median of these three as our best estimate of the co-occurrence. The Pearson correlation between rows was conducted on this matrix.[2]

One can factor analyze this correlation matrix. Table 2 is a varimax rotation of the principle components analysis of this matrix. The five factors that emerged prior to an eigenvalue falling below 1.0 represent 86% of the variance in the original matrix. An examination of the factor structure provides evidence both about the pattern of co-occurrences and the underlying motivations represented by the marker behaviors and about the association of closed- and open-mouth smiling with these underlying motivations.

On what factors did smiling load highly? Factor 3 seems to represent a social motivation. Talking, being talked to, looking at another, and not looking down or away all load highly on this factor. Closed-mouth smiling has its highest loading on this factor, and in addition, open-mouth smiling and laughing both loaded highly here. This result supports the previous analysis and clearly suggests the social motivation underlying both closed- and open-mouth smiling and laughing.

Table 2
Component Analysis of Similarities in Co-occurrence

Behavior	Factor 1	2	3	4	5
Tight lip	*−87*	02	−34	08	−03
Head shake	*−85*	−24	13	23	−01
Laugh	*84*	−00	31	18	−30

Look away	−09	−22	−47	16	*−67*

Note. Decimal points have been omitted. Loadings greater than or equal to 60 are shown in italics.

Smiling shows a complex pattern of relationships with the emotional displays. Factor 2 represents the explosive emotional displays associated with extreme scores: good scores and positive exclamation loaded highly, and

[2] In Replication 1, closed-mouth smiles were not distinguished from open-mouth smiles and looking down was not distinguished from looking away. In computing the matrix of median gammas, the undifferentiated categories of Replication 1 were generally averaged with each differentiated category of Replications 2 and 3. For example, the association between smiling and grooming in Replication 1 contributed in the final matrix to both the association of closed-mouth smiling and grooming and the association of open-mouth smiling and grooming. However, in a few cases closed and open smiles and looking down and away had substantially different associations with another behavior in both Replications 2 and 3 (mean difference in gamma > .30). In these cases, Replication 1 was ignored in computing the final measure of association. Specifically, Replication 1 was ignored in computing the median relationship of closed- and open-mouth smiling to laughter and to face cover.

negative exclamations loaded negatively. The association of closed-mouth smiles with this set of behaviors may reflect the role of closed-mouth smiling in the communication of emotion. Factor 1 seems to represent the contrast between affect and playfulness. The tight lip, head-shake, and looking-down displays cluster at one pole; and laughter, face covering, and open-mouth smiling cluster at the other. This factor may reflect the incompatibility of genuine playfulness with feeling bad.

Factors 4 and 5 are especially difficult to interpret. Factor 4 primarily represents the contrast between hamming and positive exclamations, on the one hand, and grooming, on the other. Factor 5 may indicate expressiveness. The neutral and looking-away displays are at one extreme, and open-mouth smiling and face covering are at the other.

In summary, both the temporal co-occurrence of smiling with other behaviors and the factor analysis of similarities of co-occurrence suggest that bowlers smiled when they were being social, when they were being playful, or when they were otherwise communicating an emotional statement to an audience. Both closed-mouth and open-mouth smiling shared a nonemotional, social motivation. In addition, open-mouth smiling was similar to laughter in adding a playful motivation; to the extent that one cannot be playful and at the same time distressed, angry, or disappointed, open-mouth smiling was incompatible with negative affect.

Study 2: Bowlers Facing the Pins or Their Companions

One might dismiss our failure to find a strong association between smiling and emotional experience in Study 1 with the claim that bowlers were masking their emotional experiences; they hid the joy or disappointment they felt in order to appear modest or sportsmanlike. To meet this objection we made observations of people who were bowling alone and were therefore under no pressure to mask their emotions. Lone bowlers rarely showed any facial displays or other gestures but instead maintained a generally neutral face. The most common expressions seen were relatively antisocial or negative—looking down, tight lips, and negative exclamations; they rarely smiled. However, one may object to these data, since people who bowl alone may be the type of person who is unexpressive in all circumstances.

Table 3
Percentage of Bowlers Smiling According to Bowling Score and Social Focus

Social focus	Score		
	Good	Not good	Total
Yes	42	28	31
No	4	3	3
Total	46[a]	31[b]	—

Note. $N = 116$.
[a] $n = 26$.
[b] $n = 90$.

Therefore, to further examine the social and emotional messages of smiling, we looked at bowlers when they were facing the bowling pins and reacting to their rolls, and at the same bowlers when they turned to face their friends. The social hypothesis would lead us to expect very little smiling as bowlers faced the pins, since this is a relatively nonsocial setting. The emotional hypothesis would lead us to expect that bowlers would smile after rolling a good score and would engage in behaviors revealing negative affect after bad scores, regardless of their social orientations. When bowlers roll a good score and remain facing the pins, they should feel happy and should not need to mask or hide the expression of this emotion, since they believe that they are not being observed.

Method

An observer knelt on a platform among the pin setting equipment at the end of the bowling alley behind the bowling pins and watched bowlers through binoculars as they finished their roll. The observer was 19.2 meters from the bowlers and observed through a narrow slit in the facade of the pin setting equipment. The observer was invisible to bowlers. As bowlers finished their roll and stepped back while watching its outcome, the observer recorded characteristics of the bowler and the behaviors listed above. Data were recorded from the moment the bowler stepped into view until he turned toward

the pit. Simultaneously, a second observer positioned as in Study 1 recorded behaviors in the standard way after the bowler turned to face friends in the pit. One hundred and sixteen rolls from 34 bowlers were observed from both positions (behind the pins and facing the pit).

Results

As shown in Table 3, bowlers were generally unexpressive while facing the pins, in comparison with their behavior when they faced their friends in the pit. Smiles were particularly rare. In 116 observations, bowlers smiled 36 times when facing friends but only 4 times while facing the pins, $t(115) = 6.25$, $p < .001$. Smiling was unrelated to how well they bowled. Only one of the pin-facing smiles was after a good score, although bowlers in this sample rolled 26 strikes or spares. These data clearly support the social hypothesis. People rarely smiled in nonsocial settings, regardless of emotional experience.

Study 3: Smiling by Fans at a Hockey Game

Hockey at Cornell University is probably the most important school sport. Students, faculty, and townspeople line up overnight to get season tickets. In 1977, Cornell's team had finished its regular season first in the Ivy League and was in the playoffs for the Eastern College Athletic Conference Championships. On March 8, 1977 the team faced Rensselaer Polytechnic Institute in the quarter-final at Cornell. As might be expected, the game was sold out, mainly to enthusiastic Cornell fans. Given this situation, the emotional hypothesis about the causation of smiling would predict that Cornell fans would smile more when the hockey match was going well for Cornell than when it was going well for the opposing team. On the other hand, the social hypothesis would predict that fans would smile more when socially interacting with other fans than when watching the game.

Method

A photographer sat in the stands during the hockey game and, using a telephoto lens, took pictures of the spectators across the ice from him (about 30 meters away) immediately following events favorable, neutral, or unfavorable to Cornell's chances of winning the hockey game. About 220 people were photographed at each exposure ($M = 223$; $SD = 21.8$). The photographer used a prefocused camera on a tripod and took pictures while watching the hockey game in order to be uninfluenced by the behavior of his subjects as he was photographing them. Photographs were taken after (a) goals for Cornell or the opposing team, (b) penalties called on Cornell or the opposing team, (c) face-offs, before the puck came into play, and (d) time-killing passes of the puck at center ice. Cornell goals and opposing-team penalties were considered events favorable to Cornell, the opponent's goals and Cornell penalties were considered unfavorable, and face-offs and center-ice passes were considered neutral. The section of the stands that was repeatedly photographed mainly contained season ticket holders and was filled with Cornell fans. There were few opposing fans in the entire arena, and they were segregated in another area.

Each transparency was coded by a person naive to both the hypothesis of the study and the events preceding the photograph. Five randomly selected transparencies were then recoded by a second person to check reliabilities. The transparencies were first scanned for social units, which were defined as a group of two or more spectators, at least one of whom was turned towards the other or others in the group. The two independent coders agreed on 73% of the social units that either identified. Each member of a social unit was defined to be socially involved with others in that unit, and all other spectators were defined to be socially uninvolved. The transparencies were next coded for smiling. The two coders agreed on 73% of the smiles that either identified, 69% for smiles within social units, and 74% for other smiles.

Table 4
Percentage of Spectators Smiling According to Valence of Hockey and Social Involvement

Social involvement	Valence of play for home fans: Good %	Good *n*	Not good %	Not good *n*	Total %	Total *n*
Yes	27	59	22	165	23	224
No	12	1,258	2	2,244	6	3,502
Total	13	1,317	3	2,408	7	3,726

Results

Because the results involving neutral and bad events didn't differ substantially from each other, they have been combined in the analyses that follow. Table 4 shows the per-

centage of fans smiling who were or were not part of a social unit following events that were good or not good for the Cornell hockey team.

We coded a total of 3,726 faces in 16 photographs. Over all photographs, the probability of any one of these faces smiling at the moment that the picture was taken was .069. Some data supported the emotional hypothesis. Spectators were more likely to smile following events favorable to the home team (13%) than following neutral or bad events (4%; $\gamma = .60$; $N = 3{,}726$; $p < .001$). Some data supported the social hypotheses. Regardless of the valence of the events that preceded the photograph, spectators were more likely to smile if they were members of social units (23%) than if they were not (6%; $\gamma = .66$; $N = 3{,}726$; $p < .001$). The effects of being socially involved on smiling were stronger following bad and neutral events ($\gamma = .85$) than following good ones ($\gamma = .45$, $p < .01$), perhaps because the base rate of smiling was lower following bad events.

Study 4: Smiling, Social Interactions, and the Weather

People feel happier on days when the weather is nice. Given this assumption, the emotional orientation would lead us to expect that people walking outdoors would smile more in pleasant than unpleasant weather. As they walk, they can either be socially involved with someone or not. The social orientation would lead us to expect that people would smile more if they are socially involved but that the weather alone should not influence the frequency of smiling.

Method

A single observer made observations of pedestrians twice at each of four public walkways in Ithaca, New York in September and October 1977. Each site was observed once during pleasant weather, when the temperature was between 50 and 70° F. and the sky was sunny or partly sunny, and once during unpleasant rainy weather. Pairs of observations were made at approximately the same time of day and were made within 3 weeks of each other. A total of 663 subjects were observed in the eight observation periods.

Table 5
Percentage of Pedestrians Smiling According to the Weather and Social Interaction

Social interaction	Weather: Good %	Good *n*	Bad %	Bad *n*	Total %	Total *n*
Yes	61	61	57	60	59	121
No	12	264	5	288	8	552
Total	21	325	14	348	—	—

At the site, the observer selected two reference marks about 10 meters apart on the sidewalk to indicate the limits of observation. The next pedestrian approaching the starting mark was selected as a subject. If pedestrians were walking in pairs or larger groups, the person on the extreme left or the person on the extreme right was alternately selected as the subject for that group, before the group passed he starting mark. Subjects were observed for the 8 to 12 seconds it took them to walk between the two reference marks. If they talked to anyone, greeted anyone, or were talked to by anyone at any time during the observation period, they were classified as socially interacting during that period. If they smiled at any time during the observation period, they were classified as smiling during the observation period. Reliability of the smile classification, based on a second observer's judgments of 100 pedestrians, was high ($\phi = .86$).

Results

Table 5 shows the cross classification of social interaction and smiling among pedestrians during days with good and bad weather. These results show that pedestrians are no more likely to engage in social interaction on nice days than on bad ones (19% vs. 17%, $\phi = .02$). They were slightly more likely to smile on nice days than on bad ones (21% vs. 14%, $\phi = .10$, $p < .01$) and were very much more likely to smile if they were conversing with or greeting someone than if they were not (59% vs. 8%, $\phi = .54$, $p < .001$). The effect of social interaction on smiling was slightly stronger on bad weather days than on good days ($\phi = .58$ vs. .47, $z = -1.41$, $p < .10$), but this interaction was minor compared to the main effect of social interaction and may not replicate.

We conducted an extensive pretest in which 1,489 subjects were observed at six sites on

the Cornell campus in the summer of 1977. Good weather was defined as between 65° F. and 75° F. with low humidity, whereas bad weather was over 85° F. with high humidity. Subjects were observed as long as they remained in sight, about 10–20 seconds, and observation times were not standardized across sites. In this pretest, subjects were again slightly more likely to smile on nice days than on unpleasant ones ($\phi = .13$, $p < .01$) and were much more likely to smile while socially engaged than when not ($\phi = .56$, $p < .001$). Here, however, social interaction had similar effects on good weather and bad weather days ($\phi = .58$ vs. $.54$, $z = .89$, $p > .10$).

In both comparisons, social interaction was thus a much more powerful predictor of smiling than was the weather. In the main study, variations in social interaction accounted for 29% of the variance in smiling, whereas variations in the weather and the positive and negative emotions they may have produced accounted for about 1% of the variance in smiling.

Discussion

The Social Hypothesis

Both the present and earlier research provide strong evidence that social involvement is a major cause of smiling, independent of the smiler's emotional state. In each of the four studies described above, smiling was strongly associated with social interaction: talking to and looking at others in Study 1, facing fellow bowlers in Study 2, orienting toward other fans in Study 3, and talking to another person in Study 4. Other researchers have also found that smiling often occurs in a social context. Almost from its first appearance, smiling is socially produced and has social consequences. Human infants, from the age of 1 to 5 months, smile most in response to the human voice and the human face or abstractions of it (Sroufe and Waters, 1976). These smiles seem to be a major determinant of the bond between an infant and its caretaker (Fraiberg, 1977; Spitz & Wolf, 1946). Among nursery school children, smiles are likely to occur in the context of other social behaviors such as pointing, giving, receiving, and talking (Blurton-Jones, 1972). When nursery school children approach a stranger, they often smile, and they are more likely to approach when the stranger smiles and talks to them (Connolly & Smith, 1972). In addition, the smile appears to be a universal component of greetings (Kendon & Ferber, 1973; Eibl-Eibesfeldt, 1972). Even when people smile in response to humorous or other nonsocial stimuli, they smile more in the presence of other people than when they are alone (Mackey, 1976; Leventhal & Mace, 1970).

It could be argued that positing a separate social cause for smiling is a theoretical extravagance. According to this view, the presence of others is just one of the many events that make people happy, and apparent social smiling is mediated by the pleasant emotions the smiler feels in the presence of others. This is undoubtedly true on occasion.

However, there are several reasons to believe that many smiles have purely social causes independent of happiness. The first is parsimony. We need not assume that happiness is a cause when we have evidence of a strong relationship between social stimuli and smiling, but no evidence of a mediating emotion. A theory of friendliness displays, based on independent comparative data, can account for the empirical relationship. The component analysis of Study 1 showed a social, nonemotional motivation behind some smiling (Factor 3 in Table 2): both closed- and open-mouth smiling occurred in the same contexts as each of the social behaviors we recorded at a bowling alley. These in turn were independent of both gross and subtle emotional displays of happiness, disappointment, and anger. This evidence of purely social smiling exists even though smiling has an emotional component under some circumstances (Factors 1 and 2 in Table 2).

The existence of smiles in uncomfortable social settings is further evidence against the hypothesis that social smiles are mediated by happiness. Repeated viewings of some of our bowling videotapes convinced us that some smiling was done to apologize for an especially clumsy performance or for poor bowling, such as dropping the ball before bowling

or bowling a gutter ball immediately after bowling a strike. To examine this possibility more systematically, we have started looking at facial expressions in uncomfortable social settings. If smiling evolved from primate appeasement displays, we would expect that in humans some smiling should occur when a person is trying to placate or appease another, for example when he or she has made a mistake or has violated a social norm and is apologizing for it. An exploratory field experiment suggests that subjects smile more in an appeasement than in a control condition. In the appeasement condition, customers in a store were made to think that they had made a mistake when they interrupted a clerk busy with paperwork who told them "I'm not working here. She (another clerk) will help." In the control condition, customers were made to think that no mistake had been made ("Fine, I'll get it for you, and she will ring it up"). Customers apologized more in the appeasement (11%) than the control (0%) condition. More to the point, customers smiled more in the appeasement condition (28%), when they were presumably trying to rectify a mistake, than in the control condition (5%, $\gamma = .77$; $n = 99$; $p < .001$).[3]

Ekman (1972) also notes that people often smile when experiencing an unpleasant emotion in the presence of others, although he interprets the smile as a mask for a socially inappropriate facial expression that the emotion would cause rather than as an appeasement display. A question for future research is to determine whether an appeasement or a masking hypothesis can better account for the occurrence of smiling in tense or uncomfortable social situations.

The detailed analysis of patterns of behavior in which smiling is embedded provides additional evidence that social smiling need not be mediated by happiness. For example, Kendon and Ferber (1973) have carefully described the behavior in a greeting. They divided the greeting into three stages, a distance salutation in which the participants establish their readiness and willingness for interaction, an approach phase in which one walks toward the other (or both do), and a close salutation that is a prelude to conversation or other social interaction. During the distance salutation, the greeters orient their bodies toward each other, look at each other, and show a greeting gesture such as a head toss, an eyebrow flash, a wave, or a verbal greeting. During the approach phase they decrease the amount they look at each other, until immediately prior to the close salutation, when all participants looked at and then talked to each other. Clearly the greeters were regulating their social contact during the greeting, first agreeing to it, then postponing it, and finally engaging in it when their physical separation made it convenient.

Significantly for the present argument, smiling almost invariably occurred in both the distant and close salutation, when greeters were showing a willingness to greet each other and establish or reaffirm their relationship. Smiling occurred much less frequently and intensely during the approach phase, when the greeters were showing a temporary withdrawal from social contact by looking away from each other. Smiling thus varied with the intensity of social contact. Since emotions are often regarded as diffuse with a gradual decay, it is difficult to account for the rapid and asymmetrical shifts in smiling during a 10–20 second greeting by referring to shifts in happiness.

Through this literature review, we have tried to establish that social involvement is a major cause of smiling and that happiness does not seem to be a necessary mediator. Why do people smile in the presence of others? Drawing on comparisons of humans with other primates, Hooff (1972) argues that most human smiling is affinitive, used in the expression of sympathy, reassurance, or appeasement, that is, that the smiler's motivation is to insure the establishment and maintenance of friendly interaction. The message might be paraphrased "I am friendly" or "I would like us to be friendly for a while." This may occur when friendliness is highly probable, as when two old friends greet each other after an absence, or when friendliness is problematic, as when a client interrupts a conversation between two professionals to ask one of them a question. The smile is an evolu-

[3] Peter Goldenthal, Lou Zambello, and Donna Brown planned and conducted this study.

tionarily designed signal to smooth interaction among members of a species who must cooperate in group living.

The Emotional Hypothesis

In our studies smiling had a weaker and more erratic association with happiness than it had with social interaction. Although people smiled when shouting, jumping, and gesturing after bowling a spare or a strike or when cheering their hockey team's goals, they did not smile much when they had gotten a good bowling score and were alone or had not yet turned to face their friends, or when they were walking down the street alone on a nice day. Given the very strong link between smiling and the experience of pleasant emotions posited by both the popular culture and the 100-year-old Darwinian tradition, our failure to document this link convincingly demands explanation. We will discuss three attempts to reconcile our results with the happiness hypothesis.

First, we may have found more smiling when people were social than when they were happy because our independent variables were not equated for strength. If bowling, hockey games, and walks on fine days do not produce strong pleasant emotions, they could not be expected to produce much smiling either. We believe that in general, smiling as a display of happiness is relatively infrequent in daily life, partly because the strong emotions that may be needed to elicit it are also rare. However, this is not a plausible explanation for the present results. We picked settings and activities that were likely to produce variations in positive and negative emotions. Our observations suggest that strong positive and negative emotions were produced in these settings, but that they were expressed without a consistent relationship to smiling. The positive and negative exclamations during bowling were one indicator of the strength of the emotions produced. Not getting a spare or a strike led to fewer positive exclamations and more negative exclamations, head shakes, and tight-lipped displays. Thus variations in score produced variations in emotional expressions. Although we did not systematically collect data on emotional displays among hockey fans or among pedestrians, our casual observations suggest that hockey fans expressed their excitement, joy, and approval by jumping up and down, clapping, and screaming, whereas pedestrians celebrated spurts of pleasant weather, after days of Ithaca's drizzly gloom or oppressive heat and humidity, by walking with a lilt, whistling, and humming, not by smiling.

A second possibility is that although smiling did indeed have a strong association with happiness, our subjects masked their emotional expressions according to cultural display rules, to confuse their audiences, or to comply with felt normative pressures (Ekman, 1972). They refused to smile when they felt good and used smiling as a mask for negative emotional expressions when they felt bad. However, this too is an unlikely explanation for our results. In both the bowling and hockey settings, subjects were very expressive, probably much more so than in other settings of daily life. For example, the frequency of positive and negative exclamations among bowlers and the strong association of positive exclamations with good scores attest to the freedom of this setting from constraints on emotional expression. In addition, as mentioned earlier, bowlers smiled least when they were alone or were facing away from fellow bowlers and were thus under the least pressure to use display rules.

A third reason why our results linking smiling and happiness were not as strong as we had expected is that we may have been misled by the phrase *emotional expression*. Perhaps because they have underemphasized the functions of emotional displays, earlier commentators, including Darwin (1872/1965) and Ekman (1972), have used the phrase *expression* to mean the outward manifestation of an internal state. While this definition is correct, it is incomplete. To the extent that smiling is linked with happiness, it is an evolutionarily adapted signal that informs other members of the species about the sender's emotional state in order to influence their behavior. Thus, we should expect smiling, like other primate emotional displays such as fear (appeasement) or anger (threat), to be shown to a recipient and to be less frequently seen in the absence of an audi-

ence. This interpretation is consistent with our data. Smiling had its strongest association with emotion-producing conditions when subjects were communicating emotions in the presence of others through additional displays like positive and negative exclamations, but it was only weakly associated with emotion-producing conditions when subjects were socially uninvolved. These tentative results suggest the hypothesis for further research that emotional displays, in general, should be more frequent and more intense in the presence of others, although this trend could be modified by display rules (Ekman, 1972).

A Comparison of the Social and Emotional Hypotheses

The social and emotional hypotheses about the causation of smiling are not incompatible with each other. As we have suggested, social contact may sometimes produce happiness, which in turn may lead to smiling. In addition, people experiencing happiness may show it more in the presence of others.

It is also possible that emotional and social motivations both independently produce facial displays involving what we have termed a smile, but the morphology of the displays may differ. One possibility is that the mouth region has a different shape when expressing happiness, friendliness, or appeasement. Brannigan and Humphries (1972) and Grant (1969) have described several different smiles. Our own attempts to distinguish closed- from open-mouth smiles suggest that they have different underlying motivations, with the closed-mouth smile more purely social and the open-mouth smile more playful and possibly more emotional. Moreover, even if the mouth is the same, other components of the face may differ. The whole face, rather than just the smile per se, carries information about emotion (Ekman et al., 1972; Ekman, Friesen, & Tomkins, 1971). Although the smiling mouth may be the most salient component of a happiness display, other components may often co-occur and differentiate happiness, friendliness, or appeasement smiles. Further research on facial displays needs to move to a finer level of description and categorization in an attempt to differentiate the varieties of smiles and facial displays. Ekman and Friesen's recent work (1978) is a step in this direction.

A Comparison of the Ethological and the Expressive Traditions

The ethological approach to nonverbal communication, from which the social hypothesis derives, differs from other approaches in several ways. Most important, it has remained firmly wedded to evolutionary theory and, as a result, has stayed concerned with the functions of nonverbal displays and their social consequences. This concern with functions and consequences was clearly present in Darwin's original work (1872/1965; see his discussion of the principle of antithesis), but was lost as the study of emotional expression passed through experimental psychology. The expressive approach to nonverbal behavior, from which the emotional hypothesis about smiling derives, has focused on the correspondence between individuals' internal states and their facial and other expression. As a result it has often embedded the study of nonverbal behavior in individualistic psychology by treating individuals as socially encapsulated. It is true that the expressive approach has studied communication in the limited sense of establishing that information about emotions can be transmitted through facial expression. With its almost exclusive reliance on the recognition experiment, however, this approach has not shown that people use information from facial expressions in daily life.

The effects of this neglect, while perhaps unintentional, are large. Ekman et al. (1972), after reviewing more than 10[illegible] studies on the facial expression of emotio[illegible] published in the 100 years since Darwin's original work (1872/1965), found only a few that investigated causation or production of emotional displays and *none* on the effects of emotional expression on subsequent social interaction.

In contrast to the expressive approach, the ethological approach to human nonverbal behavior treats the individual as part of a social network and examines the interactions between people and the effects of nonverbal be-

havior on others. By studying usage, this approach guides investigators toward a careful, descriptive analysis of the situations in which smiling occurs. The types of situation we studied were chosen to compare the emotional and social hypotheses about the causes of smiling, but we, along with others, have not looked at its effects. Indeed, we know of no research on human nonverbal communication from any tradition that has simultaneously studied the social and motivational causes, the morphology, and the social consequences of a human display, as Hooff has done with chimpanzee bared-teeth displays. This holistic approach is the direction, we think, that future work on human nonverbal communication should take.

The Effects of Mediator Rewards and Suggestions Upon Negotiations

James A. Wall, Jr.
School of Business and Public Administration
University of Missouri—Columbia

This study investigated the effects that two mediation techniques—rewarding negotiator concessions and suggesting concessions—have upon a negotiator's bargaining and outcomes. In the study subjects served as the negotiator and opposing negotiator while a confederate acted as the mediator in four separate wage negotiations. The results revealed that (a) mediator rewards result in larger negotiator total concessions, more negotiator–opponent agreements, and higher joint outcomes than do no rewards; (b) mediator suggestions produce larger initial concessions than do no suggestions; and (c) mediator rewards and suggestions interact, in that each technique is more potent in the absence of the other.

Over the years, mediators have developed and employed a myriad of mediation techniques to facilitate negotiation effectiveness. Such methods include establishing effective lines of communication, becoming a spokesman for the weaker side, creating a formal or relaxed negotiation atmosphere, pointing out or exaggerating the costs of no agreement, removing one party's capability to bluff, coordinating concession making, sharing responsibility for the agreement, suggesting and attributing prominence to alternative solutions, and staying out of the way. Even though mediation is noted for its variety, it suffers from a lack of theoretical analysis. Today, just as over a decade ago, "there is relatively little theoretical analysis of the mediation process and even fewer results and conclusions in consequence of such analysis" (Stevens, 1963). Since a prerequisite for such an analysis is a delineation of the mediation process, the following succinct explication is proffered. Subsequently, it will serve as the base for the generation of the hypotheses.

The Mediation Process

The mediation paradigm consists of at least three individuals (mediator, negotiator, and opposing negotiator) and three relationships (mediator–negotiator, mediator – opposing negotiator, and negotiator – opposing negotiator). Consequently, the nature and outcomes of the mediation process can be considered as resulting from the main and interactive influences of (a) the personal characteristics of the three participants, (b) the nature of the three interpersonal relationships, and (c) situational factors.

The negotiation literature documents well the effects of the two negotiators' personal characteristics and their interpersonal relationships (Chertkoff & Esser, 1976; Rubin & Brown, 1975; Yukl, Note 1), and it seems logical to conclude that these effects would retain potency in the mediator's presence. Similarly, the effects of situational factors upon negotiator – opposing negotiator bargaining are thoroughly limned (Druckman,

The author thanks Dennis D. Organ for his critical reading of an earlier draft of this manuscript and the editors and reviewers for their helpful suggestions.

1971), and one can logically assume that most of these effects hold strong in a mediation paradigm.

On the other hand, the effects of the mediator–negotiator and the mediator – opposing negotiator relationships, as well as the mediator's personal characteristics, have not as yet been investigated. And similarly, the interactions of these factors with the situational factors, the negotiator's traits, and his interpersonal relationships have not been studied. The present study focuses upon the mediator–negotiator relationship.

The Mediator–Negotiator Relationship

The relationship between the mediator and each of the negotiators can be considered one of exchange in which both the mediator and negotiator receive outcomes (or rewards) and make inputs (or incur costs). Usually the mediator's primary goal or outcome is agreement between the two negotiators (Pruitt, 1971; Stevens, 1963; Warren, 1954). In seeking this goal, the mediator can concentrate on the settlements and leave the means up to the negotiators. Such techniques include the following: suggesting better alternatives to the negotiators, selecting or defending one party's proposal, overestimating the costs of not settling or the benefits of settling, and making certain viable positions salient. On the other hand, the mediator can adopt a more indirect approach and concentrate upon modifying the negotiator's behavior, expectations, attitudes, perceptions, and so forth so as to conduce or facilitate agreement. Examples of these techniques include controlling the amount of internegotiator communication, advising one party as to the other's intentions, converting overt bargaining to tacit bargaining, suggesting concessions to one negotiator, and persuading one party to undo its commitments. As for the mediator's inputs or costs, they are manifold. The mediator operates under a strict set of norms; he must contribute expertise, objectivity, social approval (or disapproval), humor, and assurances. And occasionally he pays dearly in terms of time, sleep, energy, and relaxation.

Like the mediator, the negotiator experiences rewards and costs in the relationship. The rewards obtained from the mediator include the mediator's suggestions, approvals, payments, insights, and expertise as well as information about the opponent's intentions and forthcoming behavior. As for the negotiator's inputs or costs, they can include his promises, information as to how he will act, honesty and observation of norms vis-à-vis the mediator, and concessions to the opponent.

Because the negotiator wishes to obtain high net outcomes from his relationship with the mediator, his behavior is most likely to be altered by mediation techniques that raise his rewards and lower his costs. Two mediation techniques that do so are direct mediator rewards and mediator suggestions.

Mediator Rewards

A mediation technique that should prove effective in begetting negotiator concessions to an opponent entails rewarding the negotiator for his concessions—a technique successfully utilized by President Carter in his Mideast mediations (Butler, 1978). The predicted effectiveness of this strategy (which involves giving the negotiator a large reward when he makes a large concession to his opponent, a small reward when he makes a small concession, and no reward when he makes a negative concession or no concession) is based upon the reinforcement principle that rewarded behavior is more likely to occur at a later time than is unrewarded behavior. It is also underpinned by the finding (Wall, 1977) that an opposing negotiator, by using his own concessions as rewards, can increase the negotiator's concessions. In view of the effectiveness of rewards when they are used by the opposing negotiator, who is usually perceived as an adversary, it seems that rewards should be highly effective when applied by a mediator, who is usually perceived as a neutral party.

In sum, the mediator's rewards are expected to increase the negotiator's total concessions and consequently to result in more negotiator–opponent agreements and higher joint payoffs. Since the rewards follow the

negotiator's concessions, however, they are not expected to affect his initial concession.

Mediator Suggestions

A mediation technique that should more expeditiously lead to negotiator concessions is the mediator's suggestion of concessions, which provide the negotiator with a face-saving device whereby he can make a concession and move toward agreement without a costly loss of face (Pruitt & Johnson, 1970). If the mediator's suggestion precedes the negotiator's initial concession, it is expected to increase that concession. It is hypothesized, however, that the effect upon the negotiator's subsequent bargaining and its consequences is moderated by the presence or absence of mediator rewards: Whenever the mediator does not reward the negotiator's concessions, the mediator's suggestions retain potency throughout the negotiation because the negotiator retains his need of a face-saving device. That is, he continually requires an excuse or rationalization for his concession making, and the suggestions continually provide these. Therefore, when the mediator gives no rewards, the negotiators receiving mediator suggestions continue to make large concessions to the opponent. Consequently, they make larger total concessions, reach more agreements, and share in larger joint payoffs than do the negotiators not receiving the suggestions.

On the other hand, whenever the mediator does reward the negotiator's concessions, the suggestions (vs. no suggestions) have an insignificant effect upon the negotiator's concession making because they are of little value to the negotiator. He does not need to save face in this situation, because the mediator's rewards provide a rationalization for his concessions; he makes concessions because he receives rewards for doing so.

Hypotheses

In summary, it is predicted that mediator rewards and suggestions have the following effects:

1. Negotiators receiving mediator rewards for their concessions (a) make larger total concessions to their opponent, (b) reach more agreements with their opponent, and (c) share in larger joint negotiator–opponent payoffs than do negotiators not receiving such rewards.

2. Negotiators receiving suggested concessions from a mediator make larger initial concessions to their opponent than do negotiators not receiving such suggestions.

3. An interaction between the mediator's rewards and suggestions is manifested in the negotiator's subsequent bargaining and its outcomes. In the no reward condition, the negotiators receiving mediator suggestions (a) make larger total concessions to their opponent, (b) reach more agreements with their opponent, and (c) share in larger joint negotiator–opponent payoffs than do negotiators not receiving such suggestions. The differences in the reward condition are smaller than those in the no reward condition.

Method

Subjects

The 170 subjects who participated in the experiment were undergraduate male volunteers enrolled in behavioral science courses at Indiana University. For serving as a subject each received 2 hours' credit for experimental participation.

Procedure

Two subjects and a confederate were used in each session. Upon arrival, they were randomly seated in three chairs at a round table that was partitioned into three equal segments of partitions 2 feet high connected at the middle of the table. Each segment was labeled *union representative, mediator,* or *management representative*; the subjects were placed in the two representative positions and the confederate at that of the mediator. In the instructions the subjects were informed that they were going to act as a union or management representative in four negotiations and that the mediator was an MBA student majoring in labor relations who could communicate with them any time he wished. Attached to the union and management representative's instructions was his payoff matrix (and his alone) for the first negotiation. (The management and union payoff matrices for each of the negotiations were constructed so that a gain to one side resulted in an equal loss to the other. The positive payoff areas of

the two matrices overlapped, however, so that in each negotiation it was possible for the management and union representative to agree on a mutually profitable wage. As an example, for the negotiation in which the current wage was $6.00, a settlement at $6.30 yielded a $.20 positive payoff for the management and an $.18 loss for the union. For every $.01 that the wage increased, the union gained $.01 and the management lost $.01. Therefore, if the agreement were $6.48, the management would make $.02 and the union $.00; at $6.49 both would make $.01; and at $6.50 the management would make $.00 and the union $.02.) The instructions also told the representatives that they each had $.50 and that in the first negotiation the management representative would initiate the bargaining. He was to make the first offer on his bargaining sheet and slide it through a slot on his left to the mediator. The mediator, in all conditions, was to look at the offer, make sure that no messages were written on the sheet, and pass the sheet through a slot on his left to the union representative. The union representative, in turn, was to respond with a counteroffer and pass it back to the mediator, who was to return it to the management representative. The management representative then would make his second offer, and so forth. Both representatives were informed that they and their opponent would each be allowed to make four offers in the negotiation and that failure to agree would result in a fine of $.10 to each side. As soon as an agreement was reached or the eight offers were tendered, the mediator raised his hand and the subjects were given their instructions, payoff sheets, and a bargaining sheet for the second negotiation.

The second, third, and fourth negotiations were similar to the first. The management representative made the first offer and both sides were allowed to make four offers. At the conclusion of the fourth negotiation, the subjects were asked to complete brief questionnaires. As soon as they had done so, they were paid and debriefed.

Independent Variables

Previous mediation studies (e.g., Bartunek, Benton, & Keys, 1975; Johnson & Pruitt, 1972; Johnson & Tullar, 1972) have applied the mediation technique to *both* the negotiator and his opponent. Unfortunately, such a methodology provides confounded, equivocal data. The reported effects of their mediation techniques could have resulted from the negotiator's response to the technique, from the opponent's response, or from an interactive negotiator–opponent response. To provide more unequivocal data concerning the effects of the mediation techniques, this study applied each technique only to the negotiator (management representative). In all conditions, the mediator passed notes to the opponent (union representative) on which he had checked the statement, "I have no suggestions for this round."

Mediator rewards. In the reward condition, the mediator gave the negotiator (management representative) 50% of each concession he made to the opponent (i.e., the mediator gave the negotiator $.01 for every $.02 that he conceded to the opponent) and accompanied this reward with a handwritten message that read, for example, "Here is _____ for your last offer." (The blank was filled with the appropriate monetary amount, and the specific wording of this message was varied over the different rounds.) On the sheet passed to the negotiator, the mediator also checked the message, "I have no suggestions for this round."

In the no reward condition the mediator after each round passed the negotiator a note on which he had checked the aforementioned message without adding a handwritten message.

Mediator suggestions. In the suggestion condition, the mediator on his note suggested a predetermined offer—one that exceeded the mean offer made by negotiators in a pilot study—to the negotiator prior to each round. An example of the statements used is "I suggest that you offer about $5.44 this time."

Under the no suggestion condition the mediator in each round checked the no suggestion statement.

Dependent Variables

There were four primary dependent variables under study. The negotiator's initial and total concessions were expressed as the difference between the current wage ($4.00, $5.00, $6.00, or $7.00, with the sequence randomly selected for each negotiator) and his initial and final offer, respectively. The number of agreements in the four negotiations had a possible range of 0 to 4. And the joint negotiator–opponent payoff was the sum of the two bargainers' initial credits ($.50 each) and their payoffs for agreement minus their penalties for deadlocks ($.10 each). It did not include the mediator's rewards to the negotiator.

Design and Analysis

A $2 \times 2 \times 4$ repeated measures design with two levels of mediator reward (reward and no reward), two levels of mediator suggestions (suggestion and no suggestion), and four trials (negotiations) was used to study the negotiator concessions. The number of agreements and the joint payoff were analyzed via a 2×2 design (two levels of mediator reward and two levels of mediator suggestion).

Results

Main Effects

The mediator rewards affected all facets of the negotiators' bargaining and outcomes as predicted in Hypothesis 1. Table 1 reveals that rewarded negotiators made larger total concessions to their opponent than did those

Table 1
Negotiators' Concessions

Condition	Negotiation 1	2	3	4
Reward

Total concession	.41	.41	.44	.40

not receiving rewards, $F(1, 81) = 3.91$, $p < .051$. Similarly, the rewarded negotiators reached more agreements with their opponent than did those who were not rewarded (Table 2), $F(1, 81) = 5.98$, $p < .02$, and received larger joint payoffs, $F(1, 81) = 8.52$, $p < .005$.

As for the effect of mediator suggestions, Hypothesis 2 was supported. Negotiators receiving suggestions made larger initial concessions than did those receiving no suggestions (Table 1), $F(1, 81) = 8.01$, $p < .006$.

Interactions

The mediator rewards and suggestions interacted as predicted (Hypothesis 3a) to affect the negotiators' total concessions, Table 1, $F(1, 81) = 5.92$, $p < .02$. However, the data reveal a phenomenon in addition to the one predicted. They show that as predicted, the mediator suggestions are slightly more effective in conducing negotiator concessions in the no reward condition. But they also indicate that the mediator rewards are more effective in the no suggestion condition. Thus the two techniques have analogous effects; each is more potent in the absence of the other. Corroborative but nonsignificant evidence for this conclusion is supplied by Table 2. Here it can be seen that the mediator suggestions were effective in facilitating agreements and enhancing joint payoffs only in the no reward condition. Similarly, the mediator rewards were more effective in the absence of mediator suggestions.

Within-Subject Effects

As can be noted in Table 1, the negotiators' initial concessions increased over the four negotiations, $F(3, 82) = 5.45$, $p < .002$; however, their total concessions did not exhibit this trend effect. In addition, the analysis of the negotiator's initial and total concessions revealed no significant Trend × Reward, Trend × Suggestion, or Trend × Reward × Suggestion effects.

Discussion

The principal conclusions to be drawn from this study are threefold. Mediator rewards are effective in facilitating negotiator concessions, negotiator–opponent agreements, and large joint payoffs. Second, these rewards are more effective in the absence of mediator suggestions. And finally, mediator suggestions lead to large initial concessions in both the reward and no reward conditions; however, their effectiveness abates in the reward condition so that their effects upon the total concessions are nonsignificant.

The interaction between the mediator's rewards and suggestions raises an interesting question: Why are the mediator's rewards more potent in the absence of his suggestions and his suggestions more effective in the ab-

Table 2
Negotiator–Opponent Agreements and Joint Payoffs

Condition	Number of agreements	Joint payoff
Reward		
Suggestion	2.7	.81
No suggestion	2.7	.81
No reward		
Suggestion	2.3	.70
No suggestion	1.8	.57

sence of rewards? It appears that mediator suggestions limit the effectiveness of his rewards because the suggestions place a ceiling upon the negotiator's concessions. That is, negotiators seldom will concede more than the mediator suggests. On the other hand, when no suggestions are proffered, such a ceiling is not created. The current data support this conclusion. Only six percent of the negotiators' concessions in the reward–suggestion condition were larger than the mediator's suggestions. However, 25% of the negotiators' concessions in the reward – no suggestion condition were larger than the mediator's suggestion on the corresponding round of the reward–suggestion condition. This difference is significant, $t(41) = 2.73$, $p < .01$.

With regard to the effects of the mediator's rewards upon the potency of his suggestions, the results support the argument that suggestions, in the absence of rewards, provide the negotiators with a face-saving device, allowing them to make concessions without suffering loss of face. However, when the mediator rewards the negotiators' concessions, the suggestions do not provide the negotiators with face because the rewards provide a rationalization for their concession making.

This latter proposition engenders a more thorough consideration of the role played by the mediator's rewards. The reward effects, previously reported, could be solely attributable to the change that the rewards made in the negotiator's net payoffs. Or they could be attributable to a combination of payoff modification and other influences (e.g., face-saving or salience of reward). A 2×2 factorial design with two levels of negotiator reward and two levels of payoff administration would indicate if the payoff modification was solely responsible. As in the present experiment, the reward treatments would consist of one condition (reward) in which rewards are given for concessions and a second (no reward) in which they are not. With regard to the payoff administration factor, in one condition (mediator administered) the mediator, as in the present study, would administer the reward or no reward, and in the other (matrix administered), the payoffs would be dictated entirely by the negotiator's payoff matrices. That is, under the reward – matrix administered condition, the rewards for conceding would be built into the negotiator's payoff matrices, whereas under the no reward – matrix administered condition, the matrices would contain no rewards. If the rewards (vs. no rewards) were found to have the same effect upon the negotiator's concessions in both payoff–administration conditions, one could conclude that the reward effects are attributable only to the change that the rewards make in the negotiator's net payoffs. If a larger effect resulted under the mediator-administered condition, however, one could conclude that other influences also underpin the mediator reward effects.

Since the present study applied the mediation techniques only to the negotiator, it provided an opportunity to investigate the effect that the techniques had, via the negotiator's concessions, upon those of the opposing negotiator. If the increased negotiator concessions, resulting from mediator rewards and suggestions, had generated reduced opponent concessions, then the effectiveness of the mediation would have been reduced. But if increased negotiator concessions had resulted in large reciprocal concessions or had produced no effect, their effectiveness would have been enhanced or unaffected. The analysis of the opposing negotiator's concessions revealed that neither the mediator rewards nor the suggestions altered the opponent's concession making (none of the Fs for the differences approached significance.) That is, the opponents did not reciprocate the negotiator's concessions, nor did they exploit them.

Finally, the reported results attest to the potency of both mediator rewards and suggestions when applied to only one negotiator. Since neither technique produced indirect effects in the other negotiator's bargaining, the effects of each technique would probably be enhanced by its concomitant application to the negotiator and his or her opponent. However, further research is required to determine if this is the case or if joint application would produce an interactive effect.

The Effects of Behavioral Intentions and Consequences on Judgments of the Actor and Other: An S-V-O Analysis

David A. Kravitz and Robert S. Wyer, Jr.
University of Illinois at Urbana-Champaign

An extension of Gollob's subject-verb-object model of social inference was used to investigate the effects of information about behavioral intentions and consequences on judgments of both an actor and the person toward whom the behavior is directed. Participants received one or more pieces of information about some or all of the following factors: an attribute of the actor, the actor's intentions to help or hinder the other, the actual consequences of this action (whether the other is helped or hindered), and an attribute of the other. Judgments of actors' admirableness increased with the favorableness of the adjectives describing them, the favorableness of both their intentions and the consequences of their actions, the justness of their intentions and of the consequences of their actions, and their ability to produce the consequences they intended. Judgments of the other's admirableness depended only on the adjectives describing the other and, when this adjective was not presented, on the consequences of the actor's behavior for the other. Behavioral consequences appeared to affect judgments of both the actor and the other independently of the actor's intentions. A second experiment demonstrated that the effects of information on judgments of the actor depend on the dimension of judgment in predictable ways and suggested that judgments of admirableness may be mediated by perceptions of both virtuousness and competence.

When a person's behavior has consequences for another, subsequent evaluations of both the actor and the other will often vary with the favorableness of these consequences (cf. Lerner, Miller, & Holmes, 1976; Lerner & Simmons, 1966; Walster, 1966). These evaluations are presumably based in part on the judge's assumptions about the implications of the consequences for characteristics of the persons being judged. Unfortunately, the nature of these assumptions and their possible effects have not always been identified in research performed to date. The assumptions may depend on whether the person being judged is the actor or the target of the actor's behavior and also on other available information about these persons that influences the interpretation of the behavioral consequences. Particularly important in this regard may be information about the actor's intentions and about more general personality traits of the parties involved.

The research reported in this paper investigated the nature of these contingencies and the possible assumptions underlying them. Both the actor and the target of his actions were judged on the basis of identical sets of information, and the separate contributions of different informational cues to these judgments were isolated. The theoretical and empirical issues surrounding these matters are discussed below, along with the methodology used to investigate them.

This research was performed as part of a M.A. thesis by the first author under the direction of the second and was supported in part by a University Fellowship in Psychology from the University of Illinois at Urbana-Champaign to the first author and in part by National Science Foundation Grant BNS 76-24001 to the second author.

Judgments of the Actor

To the extent that the judge perceives an actor as responsible for the consequences of

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3709-1561$00.75

his/her action, the judge's evaluations of the actor may vary with the desirability of these consequences. However, as Fishbein and Ajzen (1975, pp. 207–213) point out, there are several different criteria for assigning responsibility. One criterion is simply whether the actors are instrumental in producing the consequences that occur, regardless of whether they could have foreseen these consequences. A second criterion is whether the actors intended the consequences of their actions. According to a third criterion, responsibility may be assigned only if the consequences of the actors' behavior are unjustified in terms of social norms or standards of appropriateness. Thus, for example, an actor who intentionally harms a person about to commit a crime would be assigned responsibility according to the first two criteria described above but not necessarily according to the third, since harming a criminal might be considered justified. Fishbein and Ajzen argue that the inconsistent effects of behavioral consequences on evaluations of the actor (cf. Shaver, 1970; Shaw & Skolnick, 1971; Walster, 1966, 1967) may be partially due to a failure to control for the criteria used by judges for assigning responsibility in the experimental conditions employed to investigate these effects.

The above comments suggest that an adequate investigation of the effects of behavioral consequences on judgments of the actor may require a consideration not only of the actor's intentions to produce these outcomes but also of the characteristics of the recipient of these outcomes. That is, if responsibility is assigned simply on the basis of whether the actor caused particular consequences, the consequence information should affect judgments of the actor independently of the actor's intentions, as Walster (1966) reports. However, to the extent that responsibility is assigned on the basis of intentionality, evaluations of the actor may be based on the perceptions of the actor's intentions, independently of the consequences that actually occur. Finally, if judges take into account the justifiability for the actor's behavior, their judgments may also depend on attributes of the recipient that influence their perceptions that the actor's intentions or the consequences of his/her behavior are justified. (Thus, for example, they may evaluate someone who either helps good people or harms bad ones more favorably than someone who either helps bad people or harms good ones.) Note that responsibility could be assigned on the basis of all three criteria simultaneously. To this extent, all three factors described above could contribute independently to judgments of the actor.

In investigating these possibilities, two points must be carefully considered. First, when information is presented about intentions, consequences, and recipient characteristics in combination, configural features other than those described above may emerge and influence judgments of the actor. For example, suppose that people who appear capable of producing the consequences they intend are seen as more competent than those who appear incapable of doing so and that the former are therefore more admired. To this extent, the consistency of the actor's intentions with the consequences of his/her actions may affect judgments in a way that could not be predicted from a consideration of either intentions or consequences in isolation.

Second, the above analysis points out that a given piece of information may contribute to judgments in several different ways, depending on the information accompanying it. Thus information that an actor intends to help another may contribute positively to judgments of the actor based on the assumption that people who intend to help others are admirable. In combination with information that the actor actually harmed the other, however, these helpful intentions might be interpreted as evidence that the actor is incompetent. In combination with information that the other person is a criminal, these intentions may be interpreted as unjustified. In the latter two cases, the actor's intentions would contribute negatively to judgments of him/her. Moreover, these various interpretations of intention information are not incompatible and thus could contribute simultaneously to judgments of the actor. A complete understanding of the influence of behavioral intentions and consequences on judgments of the actor re-

quires that the relative contributions of these factors be isolated and that the manner in which their contributions combine be determined.

Judgments of the Recipient of Behavioral Consequences

At least two theoretical perspectives suggest that the consequences of an actor's behavior may influence judgments of the person who experiences these consequences. Lerner and Simmons (1966) argue that people are motivated to maintain a belief that the world is just and therefore that people deserve the outcomes they receive. As a result, people who receive bad outcomes are assumed to be bad, whereas people who receive good outcomes are considered good. Similar predictions can be derived from the social equity formulation outlined by Walster, Berscheid, and Walster (1973). These considerations suggest that people may be evaluated on the basis of the consequences that befall them, regardless of why these consequences occur.

Judgments may also be affected by the actor's intentions toward the recipient. That is, judges may assume that people whom others intend to help have more favorable attributes than people whom others intend to harm. Moreover, attributes of the actor may also play a role in these judgments. According to balance theory (Heider, 1958), people should be evaluated more favorably (+) if either a highly regarded (+) person responds positively (+) to them or a disliked (−) person responds negatively (−) to them than if a highly regarded person responds negatively or a disliked person responds positively. Thus, the effect of an actor's intentions toward another person on evaluations of the other may be contingent on the favorableness of attributes of the actor as well as on the favorableness of the actor's intentions per se.

The various factors described above may contribute to judgments simultaneously with other aspects of the information presented (e.g., general personality attributes of the person being judged). On the other hand, it is conceivable that judges do not attach equal weight to these factors, but rather base their judgments only on those features of the presented information that they consider to be most reliable. For example, when direct information about the attributes of a person is available, judges may base their evaluations of this person primarily on these attributes while disregarding the less direct implications of others' behavior and intentions toward the person. In this case, these latter implications may have an impact only when direct information about the person's attributes is unavailable. The present study explored the possibilities discussed above.

Description of the Approach

The approach taken to investigate the issues outlined above was stimulated by the subject-verb-object (S-V-O) formulation of social cognition developed by Gollob (1974b). This formulation, which has been applied successfully to a variety of problems in impression formation and attribution (Gollob, 1974a, 1974b; Wyer, 1974, 1975; Wyer, Henninger, & Wolfson, 1975; Wyer & Hinkle, 1976) is described in detail elsewhere (Gollob, 1974b, 1979; Wyer & Carlston, 1979) and so will not be elaborated here. According to this approach, the information in a social interaction situation is analyzed by the judge into a series of *informational cues,* each cue defined in terms of values along one or more dimensions. The use of a given cue is hypothetically based on a specifiable assumption that the judge makes about its implications. Judgments can theoretically be described as a function of the independent contributions of these cues (and thus of the assumptions underlying their use), and the magnitudes of these contributions can be measured and tested statistically. The approach was originally applied to the effects of information along only three dimensions, pertaining to a trait of an actor, the actor's behavior toward another, and a trait of the other. However, it can easily be extended to any number and type of dimensions (cf. Wyer, Henninger, & Wolfson, 1975; Wyer & Hinkle, 1976). Such an extension was made in the present research.

To apply the formulation to the specific conditions of concern, consider a prototypic situation in which an actor engages in behavior that either helps or hinders another person. In such a situation, information relevant to evaluations of the actor and the other might vary along at least four dimensions, pertaining to (a) an attribute of the actor, (b) the actor's intentions to help or hinder the other, (c) the actual consequences of the actor's behavior (the other is helped or hindered), and (d) an attribute of the other. These dimensions will be denoted S, I, C, and O, respectively. If the values along each of the four dimensions are dichotomous (positive vs. negative), 16 configurations of stimulus information can be constructed, each representing a different combination of values along these dimensions.

In making a judgment on the basis of information such as that described above, judges may consider the implications of a number of different, potentially overlapping subsets of values along the dimensions involved. Which subsets they consider, and the effects of these subsets on their judgments, depends on the assumptions they make about their implications and the importance they attach to these implications. Each subset of dimension values, if considered as a basis for making a judgment, functions as a single unit of information, or *informational cue*. It is important to note that not all possible configurations of dimension values are meaningful cues: Only those configurations that have implications for the judgment when interpreted as a single unit function in this manner. Although it is often difficult to predict which of several possible cues a judge will actually use, the set of potentially useful cues can typically be circumscribed a priori.

Judgments of the actor. Based on the theoretical considerations raised above, previous research findings, and intuition, seven informational cues (referred to by Gollob as *biases*) were expected to influence judgments of the actor along a dimension of admirableness. (Admirableness rather than likableness was initially used because it seemed more directly relevant to considerations of the role of justice. However, possible differences between admirableness and other evaluative judgments are considered later in this paper.)

1. *S-bias.* Judges may assume that people with favorable attributes are more admirable than people with unfavorable ones. If this is so, actors should be judged as more admirable when the adjective describing them is favorable than when it is unfavorable.

2. *I-bias.* Judges may assume that people with good intentions (i.e., intentions to help) are more admirable than people with bad intentions (i.e., intentions to hinder). If so, their evaluations of the actor should be more positive when the actor's intentions are good than when they are not, independently of other considerations.

3. *C-bias.* Judges may assume that people who actually benefit others, regardless of their intentions to do so, are more admirable than those who hinder others. If judges make this assumption, their evaluations of the actor should increase with the favorableness of the consequences of the actor's behavior.

4. *O-bias.* Judges may assume that "birds of a feather flock together" and therefore may infer that actors are more admirable when their associates (i.e., the other) have favorable attributes than when these associates have unfavorable attributes. Although this cue is not relevant to the main concerns of this paper, it has been found to make a small but reliable contribution to judgments in previous studies (Gollob, 1968; Wyer, 1975; Wyer & Hinkle, 1976).

5. *IO-bias.* Judges may assume that people whose intentions are just are more deserving of admiration than people whose intentions are unjust. To this extent, judges should rate actors who intend either to help a good person or to hinder a bad person as more admirable than actors who intend to help a bad person or to hinder a good one.

6. *CO-bias.* People who produce outcomes that confirm that judge's perceptions of a just world may be considered more admirable than people who produce outcomes that threaten this perception. To this extent, judgments of actors who actually help a good person or hinder a bad person should be more favorable

than judgments of actors who actually help a bad person or hinder a good one.

7. *IC-bias*. Judges may assume that people who are capable of producing the outcomes they intend are more competent, and thus more admirable, than people who are incapable of doing so. To this extent, actors who actually help someone they intend to help or hinder someone they intend to hinder should be more admired than actors who help someone they intend to hinder or hinder someone they intend to help.

Note that the contributions of I-bias, C-bias, IO-bias, and CO-bias reflect the hypothetical effects of the different criteria for assigning responsibility noted earlier, whereas the contribution of IC-bias reflects the effect of an emergent cue that results when intention and consequence information is presented in combination. S-V-O methodology permits these contributions to be isolated and independently assessed, along with the contributions of more general personality characteristics of the actor and other (S-bias and O-bias).

Judgments of the other. Five informational cues seemed likely on a priori grounds to affect judgments of the person toward whom the actor's behavior was directed. The use of some of these cues is presumably based on assumptions similar to those postulated to underlie judgments of the actor, while the use of other cues is based on quite different assumptions.

1 and 2. *O-bias* and *S-bias*. As suggested above, people with favorable attributes may be seen as more admirable than those with unfavorable attributes, and people who associate with desirable others may be seen as more admirable than those who associate with undesirable others. To this extent, judgments of the other's admirableness should increase with the favorableness of both the adjective describing the other and the adjective describing the actor.

3. *I-bias*. Judges may assume that people generally try to benefit those who are admirable but try to harm those who are not admirable. To this extent, their judgments of the other's admirableness should be greater when the actor intends to help the other than when the actor intends to hinder him/her.

4. *C-bias*. People who believe that the world is just may judge someone who receives good outcomes more favorably than someone who is a victim of misfortune (Lerner & Simmons, 1966). If so, the other should be judged as more admirable if she/he is helped than if she/he is hindered, independently of other considerations.

5. *SI-bias*. Judges may assume that people are more likely to be admirable if good persons intend to help them or bad persons intend to hinder them than if good persons intend to hinder them or bad persons intend to help them. If this assumption is made, judgments of the other's admirableness should be greater in the first two cases than in the second two.

Three things may be noted from the above analysis. First, the contribution of each informational cue described above is reflected by the magnitude of one of the 15 orthogonal contrasts (main effects and interactions) in a standard analysis of variance on judgments as a function of the four informational variables. (For example, the contribution of S-bias is inferred from the main effect of the information given about the actor. Similarly, the contribution of IC-bias is inferred from the magnitude of the contrast corresponding to the interaction of intentions and consequences.) The procedures for calculating these contrasts will be described presently. Second, a single piece of information (for example, the actor's intentions) may be involved in several different informational cues, and thus may contribute to judgments in several different ways. Third, the use of a cue in judging an actor may be based on different assumptions than is the use of the same cue in judging the other.

The studies reported in this paper bear on these possibilities. The first experiment investigated the contributions of informational cues to judgments of the admirableness of both an actor and the other, and the extent to which the contributions of these cues depended upon the availability of other information. The second experiment investigated the effects of similar information on judg-

ments of the actor with respect to two other characteristics, competence and virtuousness (goodness), that were assumed to mediate judgments of admirableness. These data provided further clarification of the cues defined above and the assumptions underlying their use.

Experiment 1

Method

Overview

Forty-eight introductory psychology students judged the admirableness of two persons on the basis of information that varied along four dimensions concerned with (a) an attribute of the actor, (b) an attribute of the other, (c) the actor's intentions to help or hinder the other, and (d) the actual consequences of the actor's behavior for the other (helped vs. hindered). Each type of information was varied independently in a 2^4 design with two different stimulus replications. In addition to the 16 stimuli comprising the complete design, subjects made judgments of stimuli composing all possible subsets of the information dimensions given above. Data were analyzed using S-V-O methodology in a manner described below.

Subjects

Fifty-one undergraduates participated in the study to fulfill a course requirement in introductory psychology. Of these, 3 who failed to provide complete data were subsequently dropped from the analyses. Participants were run in groups of from 8 to 12 in sessions of approximately 1 hour. Subjects were verbally debriefed upon completion of the questionnaire.

Construction of the Questionnaire

Each stimulus in the main section of the questionnaire consisted of from one to four sentences describing an interaction between two people. These stimuli were constructed by factorially varying information along four dimensions concerning an attribute of the actor (S), the actor's intentions (I), the actual consequences (C) of the actor's behavior for the other, and an attribute of the other (O). There were two levels of each factor.[1]

To ensure that the results obtained were not peculiar to a given set of stimulus materials, these materials were constructed at two levels of abstractness. Moreover, different trait descriptions were used to describe the actor and the other in the two sets. Each set of materials was administered to a different group of subjects. The *concrete* materials concerned a specific business situation in which the actor and other were described as either tolerant or intolerant, and the actor's intentions (or consequences) dealt with having the other transferred to another department of the corporation for which they both worked—a transfer that the other either did or did not desire. Thus, for example, the stimulus for the condition in which values along S and I were both positive and values along C and O were both negative was of the form: "A is a tolerant person. A intends to have B transferred to another department, where B wants to work. As a result of A's actions, B is transferred to department where B does *not* want to work. B is an intolerant person."

The *abstract* materials contained information about a less clearly specified situation in which the actor's intentions and the consequences of his/her behavior were described simply in terms of helping and hindering. Moreover, the attributes describing the actor and the other were either honest or dishonest rather than tolerant or intolerant as in the concrete materials. Thus, the stimulus representing the same condition as in the preceding example was of the form: "A is an honest person. A intends to help B. B is hindered by A. B is a dishonest person."

In all, 80 sets of information were presented in each stimulus replication. Of these stimuli, 16 contained information concerning all possible combinations of values along the four dimensions. These stimuli comprised the complete (SICO) stimulus design. The remaining 64 stimuli formed all possible subdesigns, each pertaining to a different subset of information dimensions. Specifically, subjects were presented with the eight stimuli forming each of the SIC, SIO, SCO, and ICO subdesigns, the four stimuli forming each of the SI, SC, SO, IC, IO, and CO subdesigns, and the two stimuli comprising each of the S, I, C, and O subdesigns, where the letter(s) symbolizing each design pertain to the dimension(s) along which information was varied.

Stimuli were presented in three subsections of the questionnaire. One subsection contained those stimuli with information about both I and C (i.e., those comprising the SICO, SIC, ICO, and IC designs); a second subsection contained stimuli with information about C but not I (those comprising the SCO, SC, CO, and C designs); and the third subsection contained stimuli with information about I but not

---

[1] The information presented (with the exception of "help" and "hinder") was chosen on the basis of a pretest. Twenty-three subjects were presented with a number of personality traits, intentions, and consequences, and were asked to rate "how good each individual trait, intention or consequence is." The stimulus pairs used were chosen so that the negative member was as far below the neutral point as the positive member was above it. The intention and consequence information used in the abstract stimulus materials (help and hinder) was chosen to relate to previous work in the area (cf. Gollob, 1974a; Wyer, 1974).

C (those comprising the SIO, SI, IO, and I designs). The remaining stimuli, comprising the SO, S, and O designs, were randomly distributed within each of the three subsections. Stimuli were ordered randomly within each subsection except that the stimuli expected to produce the most extreme judgments were presented first in an attempt to anchor the response scale. These subsections were presented in all six possible orders to control for any demand characteristics that might be engendered by the presence or absence of specific information.[2]

After receiving each stimulus, subjects estimated how much they admired both the actor and the other along 11-point scales that ranged from 0 (not at all) to 10 (extremely much). The order of these estimates was counterbalanced across subjects.

Thus 84 stimuli were contained in the main section of the questionnaire (80 unique stimuli and 4 repetitions; see Footnote 2), with each stimulus requiring two responses.

Results

Judgments of the Actor

Data pertaining to the complete design and to each of the 14 subdesigns were analyzed separately. In each case, analysis of variance was first performed on judgments, collapsed over order of stimulus presentation and order of response, as a function of the four information dimensions presented (S, I, C, and O) and the type of stimulus materials (abstract vs. concrete). The main effect of stimulus materials was not significant in any of the 15 analyses, and few effects of informational variables were significantly contingent on scenario. The only exception to this concerned the interaction of stimulus materials with information about the actor (i.e., the information along S), which was significant in all 8 designs that included this information. These interactions indicated that the effect of the trait assigned to the actor in the abstract materials (honest vs. dishonest) was greater than the effect of the trait assigned to him/her in the concrete materials (tolerant vs. intolerant). This contingency simply reflects the difference in the implications of these traits for admiration and has no theoretical relevance to the issues of central concern in this paper. The few other interactions involving stimulus materials had no obvious psychological meaning and were interpreted as spurious.[3] Subsequent discussion is therefore restricted to data pooled over the two stimulus conditions.

An analysis of judgments as a function of the four informational variables involved in the complete (SICO) design yields 15 possible main effects and interactions. Of these, 7 (the 4 main effects and the two-way interactions between intentions, consequences, and the attribute describing the other) correspond to the information cues expected on a priori grounds to contribute significantly to judgments of the actor (S-bias, I-bias, C-bias, O-bias, IC-bias, IO-bias, and CO-bias). To calculate the orthogonal contrasts assumed to indicate the contributions of these cues, the favorable pole of each informational dimension was assigned a positive (p) valence and the unfavorable pole was assigned a negative (n) valence. The contrast corresponding to a particular effect was then computed by subtracting (a), the mean judgment of stimuli in which the product of the relevant valences was negative, from (b), the mean judgment of stimuli in which the product of the relevant valences was positive. (Thus, for example, the contrast corresponding to the interaction of I and O, which indicates the contribution of IO-bias, was inferred from the difference between the mean judgment based on stimuli in which the valences of I and O were both p or

---

[2] To investigate the possible effects of presentation order, four additional stimuli comprising one of the two-factor designs that appeared in the first subsection of the questionnaire were repeated in the third subsection. The specific two-factor designs used were varied over subjects. Comparisons of these two sets of judgments revealed no significant differences, suggesting that order was not an important factor in this experiment.

[3] In only three designs did stimulus materials interact with any factor other than S. In these cases, the two sets of stimulus materials were analyzed separately. In only one instance did these separate analyses result in a significant effect in the opposite direction from that of the combined data; specifically, the effect of O was negative in the ICO design when the abstract stimulus materials were used. In all other cases, the effect obtained using abstract materials was greater than that obtained using the concrete stimulus materials, but both effects were in the same direction. These interactions included CO in the CO and ICO designs and IO in the IO design.

*$F(1, 42) > 4.08$, $p < .05$. **$F(1, 42) > 7.31$, $p < .01$.

n and the mean judgment based on stimuli in which one of these valences was *p* and the other was *n*.) These contrasts are shown in Table 1 for the complete design. Similar contrasts, based upon analyses of each subdesign, are also presented. (Statistical significance in each case is based on a separate analysis of data for each subdesign.)

According to the assumptions hypothesized to underlie the use of each cue and the notational system used to compute its contribution, the contrast associated with each cue should theoretically be positive. In fact, all contrasts but that corresponding to O-bias were significant and positive in the complete design. Moreover, the six cues that contributed significantly to judgments in the complete design contributed significantly to judgments in the subdesigns in which they were presented in 29 of 30 cases. The nonsignificant contribution of O-bias in both the complete design and subdesigns is not too surprising, since the magnitude of this cue was quite small in previous studies (Gollob, 1968; Wyer & Hinkle, 1976). Overall, the 7 contrasts described in Table 1 and interpretable on a priori grounds as reflecting the contributions of informational cues accounted for 97% of the item set variance in the complete design, whereas the 8 interactions that were *not* predicted to contribute to judgments accounted for only 3% of the variance. Moreover, these latter interactions were significant in only 4 of the 13 relevant subdesigns (31%), as opposed to 29 of 37 instances (78%) in the case of the seven predicted effects. None of the significant unpredicted effects qualifies our conclusions concerning the predicted effects of informational cues; in all cases, the contributions of these cues remained in the expected direction, varying only in magnitude.

Nevertheless, the nature of the few unexpected effects may be worth noting briefly. The only unexpected interaction that approached significance in the complete design involved S, I, and C; $F(1, 47) = 8.63$, $p < .01$. This is less than the Bonferroni critical value of 9.73 for 15 comparisons and the .05 significance level (Myers, 1972). To the extent that this interaction is taken seriously, it may best be interpreted as an indication that the contribution of IC-bias is greater when the actor is described by a favorable attribute

(M contrast = .64) than when the actor is described by an unfavorable attribute (M contrast = .12). The use of IC-bias presumably reflects the assumption that people are more admirable if they produce outcomes they intend than if they do not. The possibility that this assumption is made only when the actor has other favorable qualities has some intuitive appeal; if the actor is described by an unfavorable attribute, this may be sufficient to conclude that she/he is not admirable, and judges may thus attend less to other cues. However, since this interaction did not even approach significance in the SIC subdesign, the above interpretation should be treated with caution pending replication of the effect.

Three of the four unpredicted significant effects in the subdesigns pertained to the interaction of S and I. The interpretation of this interaction, which was not significant in the complete design, is unclear. It could reflect a tendency for judges to assume that people are more admirable if their intentions are evaluatively consistent with their general personality attributes (both favorable or both unfavorable) than if they are evaluatively inconsistent. Alternatively, it may also indicate that judges pay more attention to an actor's intentions when the actor is described by a favorable adjective than when he is described by an unfavorable one, and so I-bias has more effect in the former condition than in the latter. (This interpretation is consistent with our tentative interpretation of the SIC interaction.) Finally, the interaction could be due to a floor effect produced by the unavailability of sufficiently extreme responses (on the response scale) when both the adjective describing the actor and his intentions were unfavorable. If this is the case, however, it occurred despite our attempt to stabilize the response scale by presenting the stimuli calling for the most extreme responses first.

Summary. The results described above provide support for several general hypotheses raised in the introduction. First, they suggest that responsibility for behavioral consequences may be assigned according to several different criteria, and that each contributes to evaluations of the actor. That is, responsibility may be assigned simply on the basis of the actor's having committed the act that produced these consequences (leading C-bias to contribute to judgments), on the basis of the actor's intentions (leading I-bias to contribute), and on the basis of the justifiability of these intentions and consequences (leading IO-bias and CO-bias to influence the judgments). In addition, judgments of the actor may be based on other factors, including more general dispositional characteristics (as reflected in the contribution of S-bias) and the ability to produce the outcomes she/he intends (as evidenced by the contribution of IC-bias). It should be noted, however, that while the contributions of these cues may be isolated within any given design in which they occur, this does not imply that the contributions of some cues are unaffected by the availability of others. We shall return to this possibility presently.

Judgments of the Other

Judgments of the other were analyzed in the same manner as were judgments of the actor. Once again, no main effects of stimulus materials were significant, allowing us to pool data over this factor.[4]

Five main effects and interactions, corresponding to the informational cues denoted S-bias, I-bias, C-bias, O-bias, and SI-bias, were postulated on a priori grounds to be significant. The contrasts corresponding to these effects, calculated in the manner described previously, are shown in Table 2 for both the complete design and the subdesigns to which they are relevant. While all contrasts were positive as predicted, only that corresponding to O-bias was significant in the complete design. This suggests that when direct information about attributes of the other is avail-

[4] In only three designs did stimulus materials interact with any factor other than O. In these cases, the two sets of stimulus materials were analyzed separately. In only one instance did these separate analyses yield an effect that was significantly different in direction from those reported in Table 2: The effect of S was in reverse direction in the SIC design with the concrete stimulus materials.

Table 2
Contributions of Predicted Informational Cues to Judgments of the Other

able, only this information is used as a basis for judging the person's admirableness. In this case information about other people's intentions and reactions to the person has relatively little influence.

When trait information about the other is not available, however, the actor's intentions and reactions toward him/her appear to have more effect. Specifically, I-bias, the use of which is presumably based on the assumption that people are more apt to be admirable if someone intends to help them than if someone intends to hinder them, contributed significantly to judgments of the other in two of the four subdesigns in which trait information along O was not presented, and was nonsignificantly greater in these four subdesigns (M contrast = 0.27) than in the four designs in which information along O was available (M contrast = 0.13), $F(1, 47) = 1.74$; $p > .10$.[5] Similarly, the contribution of C-bias, presumably based on the assumption that good things occur to good people and bad things occur to bad people, contributed significantly to judgments in three subdesigns, two of which were also those in which trait information about the other was not presented. The mean contribution of C-bias when information along O was not available was nonsignificantly greater (M contrast = 0.41) than its contribution when the information along O was also presented (M contrast = 0.25), $F(1, 47) < 1$ (see Footnote 5). Although these differences are not reliable, their consistency is sufficient to suggest that judges are most likely to infer the admirableness of people on the basis of others' intentions toward them and the consequences of others' behavior toward them when direct information about the attributes of these people is not available.

Although it was statistically significant in only three of eight cases, the contribution of C-bias to judgments of the other was consistently positive in all eight designs in which information along C was presented. (The probability of this result, assuming the strict null hypothesis, is approximately .004.) The contribution of this cue supports Lerner and Simmons's (1966) hypothesis that people infer the characteristics of others from the outcomes the others receive in a way that maintains their image of a just world. In this regard, it is also worth noting that intention information was also presented in all cases in which the contribution of C-bias was significant. Thus, the contribution of consequences information to judgments of admirableness of the other cannot be attributed solely to its mediating effects on beliefs about the actor's intentions to produce these consequences. Rather, consequences information has an effect over and above that of intentions. We shall return to this matter presently.

Of the 10 interactions that were not interpreted a priori as reflecting the contribution of informational cues, only 2 (SICO and CO) were significant in the analysis of the com-

[5] This analysis was performed on the mean contributions of the four relevant designs, with subjects being the replication factor.

plete design. Moreover, the proportion of item set variance accounted for by these 10 interactions was only 2%, as compared to 98% for the 5 effects that were predicted. Finally, the unpredicted interactions were significant in only 1 of 19 instances in which the relevant factors were manipulated in the various subdesigns. None of the 3 unexpected effects had any obvious psychological meaning, and none represented a significant reversal in the direction of the contributions of any informational cue described in Table 2.

Combinatorial Processes

Judgments of the actor, unlike judgments of the recipient, appeared to be based upon several different informational cues. A question therefore arises concerning the manner in which the implications of these cues are combined to influence the judgments. There are at least three obvious possibilities. First, as noted previously, judges may use only a limited number of informational cues as a basis for their responses (cf. Wyer, 1974; Wyer et al., 1975). If this is so, the likelihood that any given cue is used may decrease with the total number of cues available. The other possibilities are suggested by the research on algebraic models of information integration (cf. Anderson, 1971, 1974). That is, judges may first construe the implications of each informational cue separately and then either average or sum these implications to arrive at an overall judgment. If the implications of a given informational cue remain invariant over the stimulus configurations in which the cue is contained, an averaging model also implies that the contribution of this cue will decrease with the number of cues available (since the relative weight given to it will be less). On the other hand, a summative model implies that the contribution of each cue will not be affected by the number of other cues present.

To explore these possibilities, the mean contributions of the informational cues that contributed significantly to judgments of the actor in the complete design were plotted as a function of the number of factors comprising the design. (While the number of dimensions along which information is presented is not a perfect indicator of the number of informational cues available, this criterion was used in order to eliminate the need for a priori assumptions concerning the nature of these cues and whether they would contribute significantly.) These data are shown in Figure 1. In each case, the contribution of the cue decreased in magnitude with the number of informational dimensions comprising the design. This conclusion is supported statistically by the results of linear trend analyses of the data in each panel of Figure 1.[6] These trends were significant in analyses of S, $F(1, 141) = 70.64$, $p < .01$; I, $F(1, 141) = 89.27$, $p < .01$; C, $F(1, 141) = 54.23$, $p < .01$; IO, $F(1, 94) = 9.92$, $p < .01$; and CO, $F(1, 94) = 15.35$, $p < .01$ The linear trend for IC was nearly significant, $F(1, 95) = 3.15$, $.05 < p < .10$. These data rule out a summative process of information integration. However, the other two alternative possibilities raised above

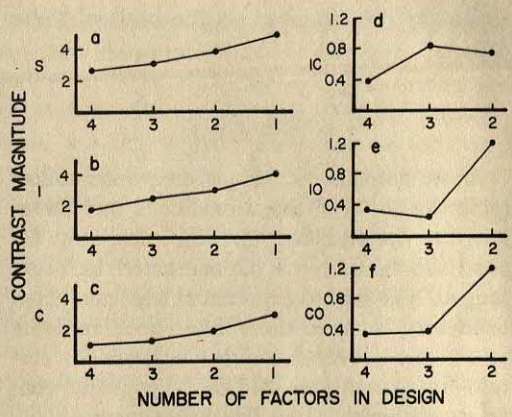

Figure 1. Mean contributions of (a) S-bias, (b) I-bias, (c) C-bias, (d) IC-bias, (e) IO-bias, and (f) CO-bias to judgments of the actor as a function of the number of factors in the design.

[6] These analyses were performed on the mean contribution of the given cue in all of the designs of the same size (1, 2, 3, or 4 factors), with subjects being the unit of analysis. Thus, for example, the value for the contributions of S were based on a single design for Design Sizes 1 (S) and 4 (SICO) and on the mean of three designs for Design Sizes 2 (SI, SC, SO) and 3 (SIC, SIO, SCO).

cannot be distinguished on the basis of these data.[7]

Experiment 2

As we noted earlier, the assumptions underlying the use of informational cues, and therefore the contributions of these cues, may depend substantially on the characteristic being judged. The second experiment was conducted to identify some of these differences. In doing so, it also provided indirect support for certain interpretations of the significant contrasts obtained in the first experiment.

Admiration for people may be based on two general types of criteria, both of which were reflected in the informational cues that contributed to judgments in Experiment 1. On the one hand, a person may be admired because she/he is virtuous, that is, his/her attributes and behavior coincide with social standards of morality and justice. Thus, the contributions of I-bias and IO-bias to judgments of the actor presumably reflected assumptions that people who intend to help others are more admirable than people who intend to hinder others and that people whose intentions are just are more admirable than people whose intentions are unjust. On the other hand, a person may be admired because she/he is particularly competent or has exceptional artistic or athletic skills, quite apart from moral considerations. This would account for the contribution of IC-bias to judgments of the actor in the first experiment, which was presumably based on the assumption that persons who are capable of producing the outcomes they intend are more competent, and therefore more admirable, than are those who are incapable of generating intended outcomes. If this reasoning is correct, it has implications for the contributions of these informational cues to judgments of the actor along dimensions other than admirableness. Specifically, all three cues mentioned above should affect judgments of the actor's admirableness, as was found in Experiment 1. However, suppose contributions of I-bias and IO-bias to admirableness judgments are mediated by their influence on perceptions of the actor's virtuousness, whereas the contribution of IC-bias is mediated by its influence on perceptions of the actor's competence. In this case, I-bias and IO-bias but not IC-bias should contribute to judgments of the actor along a good–bad dimension (assumed to be an index of virtuousness), whereas IC-bias but not IO-bias or I-bias should contribute to judgments of the actor's competence.

Method

Two questionnaires were prepared, one pertaining to competence judgments and the other to general evaluations of the actor along a good–bad dimension. Each form was constructed using the same basic set of stimulus materials, which represented all eight combinations of bipolar values along three informational dimensions pertaining to an actor's intentions (to help vs. to hinder), behavioral consequences (helps vs. hinders), and a general description of the other (good vs. bad). Thus the information presented was comparable to that involved in the ICO subdesign of Experiment 1. This information was presented in items of the form: "S intends to help (hinder) O. O is helped (hindered) by S. O is a good (bad) person." Then, in the form pertaining to competence judgments, two items were constructed with each set of stimulus information. In one item subjects were asked to estimate how likely it was that S was competent, and in the second item they were asked to estimate how likely it was that S was incompetent. In the form pertaining to good–bad judgments, corresponding items asked whether S was likely to be a "good person" or a "bad person."[8]

---

[7] There is, in addition, a statistical problem with these data. They violate the homogeneity-of-treatment–difference–variance assumption (Huynh & Feldt, 1970). Although this does not affect the analyses previously reported, it does force us to further qualify the modeling results. Specifically, when this assumption is not satisfied, the contrasts are not uncorrelated in the population and thus there is no guarantee that the sample contrasts are the appropriate bias weights. The homogeneity-of-treatment–difference–variance test was run on the covariance matrix of the 15 contrasts of the SICO design. The contrasts pertained to judgments of the actor, and the data were pooled over both stimulus replications. For these data: $f = 104$, $d = .8967$, $W = .001$, and $-(df)(d)lnW = 290$ is compared to chi-square with 104 degrees of freedom. The correlations among the contrasts ranged from $-.499$ to $+.421$, and the mean was $-.002$.

[8] Subjects were asked about both poles of the dimension to provide a test of the "relevant bias hypothesis" proposed by Gollob (1974b). This test is beyond the scope of this report; for details, see Kravitz (1978).

In all cases, judgments were made along an 11-point scale, ranging from 0 (not at all likely) to 10 (extremely likely). The 16 items in each form were arranged randomly, except that those items expected to result in the most extreme responses were placed first in an attempt to anchor the response scale.

Fifty-one subjects who did not take part in the first experiment participated in this study to fulfill a course requirement in introductory psychology. Of these, 27 completed the form pertaining to competence judgments, and the other 24 completed the form pertaining to good–bad judgments.

Results

For each set of stimulus information, each subject's judgment of the actor with respect to the negative pole of the relevant response dimension (i.e., either "incompetent" or "bad") was subtracted from his/her judgment of the actor with respect to the positive pole ("competent" or "good"). Each difference score was then treated as a single index of perceived competence or goodness.[9] The two sets of difference scores were then analyzed separately as a function of the three informational dimensions.

The five main effects and interactions that were significant in the first experiment when admirableness judgments were made, corresponding to the contributions of I-bias, C-bias, IC-bias, IO-bias, and CO-bias, were of particular interest. The magnitudes of the contrasts corresponding to these effects, along with the other contrasts involved in the analyses, are shown in Table 3 for both sets of judgments. (In each case, contrasts were calculated in the manner described in Experiment 1.) These data show the pattern expected on the basis of the considerations noted above. That is, of the five informational cues found in Experiment 1 to affect admirableness judgments, only the cue expected to be particularly relevant to competence, IC-bias, contributed significantly to these judgments. However, this cue did not contribute to judgments of the actor along a good–bad dimension. In contrast, I-bias, C-bias, IO-bias, and CO-bias each contributed significantly to judgments of the actor along the good–bad dimension, but not to judgments of the actor's competence. Although the effects of C-bias and CO-bias were not explicitly predicted, their contributions are not incompatible with these predictions. They suggest that people whose actions have either desirable or just consequences are assumed to be better people, regardless of their intentions, than are those whose actions have undesirable or unjust consequences.

Table 3
Contrast Magnitudes for Judgments of the Actor (S) in Experiment 2

Contrast	Dimension of judgment	
	Competent–incompetent	Good–bad
I	.22	2.28**
C	.21	1.27**
IC	2.54**	.32
IO	−.01	.97**
CO	−.04	.74*

Note. S = an attribute of the actor. I = the actor's intentions to help or hinder the other. C = the actual consequences of the actor's behavior. O = an attribute of the other.
*$p < .05$, $F(1, 23) > 4.30$ for competent–incompetent and $F(1, 26) > 4.23$ for good–bad. **$p < .01$, $F(1, 23) > 7.95$ for competent–incompetent and $F(1, 26) > 7.72$ for good–bad.

In summary, the results of this experiment suggest that the effects of the informational cues on judgments of admirableness found in Experiment 1 were mediated by their implications for two different attributes, competence and virtuousness.

Discussion

In combination, the two experiments reported here provide substantial insight into the assumptions and factors that underlie the effects of behavioral consequences and intentions on judgments of the interacting parties. Moreover, they point out important differences between the factors that underlie the

[9] This approach seemed justified on a priori grounds for two reasons. First, it was expected that judgments pertaining to one pole of the dimension would correlate negatively with judgments pertaining to the other pole. Second, the use of both poles would seem to represent the dimension better than the use of a single pole. Supplementary analyses of judgments pertaining to each pole separately do not qualify the pattern of results reported (Table 3).

effects of behavioral consequences on judgments of the actor and the factors that underlie their effects on judgments of the person toward whom the actor's behavior is directed. In the first case, we speculated that judgments of the actor may be mediated by attributions of responsibility at several different levels, ranging from simply the commission of the act that produced the consequences to the actor's intentions to produce the consequences and the justifiability of these outcomes (as defined in terms of social standards of appropriateness). In fact, attributions of responsibility at all three levels appear to contribute to judgments of the actor. In addition, evaluations of the actor appear to be based upon perceptions of the actor's ability to produce the outcomes she/he intends, as well as more general dispositional characteristics implied by the adjectives used to describe him/her. In this regard, results of the second experiment suggest that judgments of the actor's admirableness may be mediated by perceptions of both virtuousness (goodness) and competence, and the contributions of these cues to admirableness ratings may be a result of their more fundamental influence on these mediating perceptions.

Whereas judgments of actors were based upon their intentions and the consequences of their behavior, judgments of recipients were significantly affected by the actor's intentions and behavioral consequences only when more direct information about the recipient's general personality (e.g., trait adjectives) was unavailable. This suggests that judges tend to ignore the implications of others' reactions to a person and the consequences of another's behavior toward this person when more direct indications of his/her personality are provided. Nevertheless, the consistently positive influence of consequences information on judgments of the other provides some support for the hypothesis that judges believe in a just world and therefore evaluate people on the basis of the favorableness of the consequences that befall them (Lerner & Simmons, 1966). Moreover, beliefs in a just world appear to enter into inferences in several additional ways. For example, actors as well as others were admired more when their behavior had good consequences than when it had bad consequences, independently of other considerations. In addition, actors were more admired when their behavior had just consequences (i.e., when they helped good people or hindered bad people) than when it had unjust consequences. This is not to say that behavioral intentions are ignored; the intentions to produce both good outcomes (I-bias) and "just" outcomes (IO-bias) also contributed significantly to judgments of the actor. However, the independent contribution of consequences information is noteworthy and suggests an extension of the role of just world considerations beyond that implied by the original formulation. That is, one's belief in a just world may not only lead one to evaluate others in accordance with the outcomes they receive (thus making one's own perceptions consistent with this belief) but may also lead one to evaluate people more favorably if their behavior has consequences that reinforce this belief.

The effects of consequences and intentions noted above are relevant to a more general issue raised earlier. That is, a given piece of information can contribute to judgments in several ways, depending on the interpretation of its implications. Moreover, these contributions may occur simultaneously. In the present case, for example, the actor's help or hindrance of the other may be considered independently of additional information presented and therefore may contribute to judgments in its own right. However, depending on the additional information available, it may also be interpreted as an indication that the actor behaved justly or unjustly or that she/he is more or less competent. Each of these interpretations has implications for judgments of the actor.

The fact that information can affect judgments in different ways emphasizes the value of S-V-O theory and methodology in conceptualizing these various effects. In this regard, it is worth noting that of the statistical contrasts postulated on a priori grounds to reflect the contributions of psychologically meaningful informational cues, six of seven contrasts contributed to judgments of the actor and two of five contrasts contributed to

judgments of the recipient. On the other hand, very few of the contrasts that were *not* clearly interpretable as informational cues contributed significantly to judgments of either the actor or the other, and these contributions were typically not consistent over the informational configurations (full design and subdesigns) in which the relevant information was presented. Thus, it should be apparent that an S-V-O formulation can serve as a heuristic framework for circumscribing the set of information factors that may influence judgments in a given situation, and for conceptualizing the possible assumptions underlying the effects of these factors.

Self-Directed Attention, Awareness of Bodily States, and Suggestibility

Michael F. Scheier
Carnegie-Mellon University

Charles S. Carver
University of Miami

Frederick X. Gibbons
University of Kansas

Two studies tested the hypothesis that self-directed attention would cause increased awareness of internal states and would thus reduce suggestibility effects. Experiment 1 applied this reasoning to the experience of an emotion. Males viewed moderately arousing slides of female nudes after being led to expect the slides to be either highly arousing or nonarousing. As predicted, ratings of the slides corresponded less with these experimentally-manipulated anticipations when self-focus was heightened by the presence of a mirror than when it was not. Experiment 2 examined a different internal experience: the perception of taste. Some subjects were led to expect a strong flavor as part of a test series, and other subjects were led to expect a weak flavor. Subjects high in private self-consciousness were less affected by this expectancy manipulation and more accurate in reporting their actual internal state than were subjects low in private self-consciousness. Discussion centers on the theoretical implications of the findings.

Casual observation suggests that many persons do not know themselves very well (cf. Nisbett & Wilson, 1977). When asked for a self-description, they provide their questioner with a picture fraught with distortions, ambiguities, and inaccuracies. Moreover, these vagaries in self-report are often unmotivated. That is, the inaccuracies exist simply because people are ignorant of their characteristics, not because of any attempt to deceive. As we all know, these impressions from everyday experience are also substantiated in the empirical literature (cf. Mischel, 1968). The correlations between self-report of behavior and actual behavior, for example, typically hover in the mid-twenties; rarely do they even reach into the thirties.

The authors express their appreciation to the following people, who assisted with data collection: Randall Heller (Experiment 1); Gaye Delevin, Russ Militello, and Steve Faloon (Experiment 2).

Requests for reprints should be directed to Michael F. Scheier, Department of Psychology, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213.

Recent research stemming from self-awareness theory (Duval & Wicklund, 1972; Wicklund, 1975), however, appears to indicate that this picture of people's self-knowledge need not always be so bleak. In particular, the theory suggests that self-focused attention may be an important determinant of the accuracy of self-reports. Presumably, a person whose attention is directed inward is more cognizant of his or her self-aspects than is a person whose attention is directed elsewhere. The heightened salience of self that occurs as a function of self-focus should be reflected in more accurate self-descriptions.

This seems indeed to be the case. In one study (Pryor, Gibbons, Wicklund, Fazio, & Hood, 1977), undergraduate men were asked for a self-report of their level of sociability; several weeks later their sociable behavior was objectively measured. The correlation between self-report and behavior for this group was .17. In contrast, when the procedure was repeated with a different group who made their self-reports in the presence of a mirror, the correlation approached .70. Related re-

search has shown conceptually similar effects for persons who are dispositionally high in private self-consciousness (Scheier, Buss, & Buss, 1978; see also Carver, 1975; Turner, 1978). In brief, self-focused attention appears to be an important moderator variable that affects the accuracy of self-reports.

The primary purpose of the present research was to explore further the relationship between self-focused attention and accuracy of self-reports. In doing so, however, an attempt was made to extend the analysis to a different domain of self-knowledge. Thus, rather than study again the link between self-report and behavior, we chose instead to examine the effect of self-directed attention on knowledge of and reports about a variety of different bodily states.

Similar considerations should apply to awareness of one's bodily experiences as apply to knowledge about one's behavorial tendencies. That is, focusing attention on the self should lead to increased awareness of any experiential dimension that is salient at the time. When attention is focused on one's prior behavior, the accuracy of the self-report of that behavior is enhanced (Pryor et al., 1977; Scheier et al., 1978). If attention is focused on one's bodily state, on the other hand, then the person's self-report about the state should similarly become more accurate. Testing this reasoning was the major objective of the present research.

Suggestibility

The present studies also allowed us to confront another issue as well. We know from previous research that internal sources of information are not the only determinants of self-reports of internal states. To the contrary, many people seem to make extensive use of information from their environments in defining for themselves what their experiences are, even when those experiences are essentially internal ones. For example, people will make use of externally provided information in determining how intense their emotions are (e.g., Barefoot & Straub, 1971; Valins, 1966). To the extent that a person utilizes external rather than internal information when making judgments about his internal states, he is open to a wide variety of suggestibility phenomena. Indeed, a person who judged his bodily states totally on the basis of his internal sensations would be completely impervious to the influence attempts of others. Such suggestibility influences on judgments of bodily states can occur in many forms. For example, phenomena that would fit into this category include "demand" effects (Orne, 1962)—that is, the influence that an experimenter's verbalizations and demeanor can have on subjects' subsequent reports—and "placebo" effects—that is, the influence that misleading information about the actions of an inert substance can have on subjects' subsequent reports. What both these effects have in common is this: The subject accepts some externally provided information indicating the nature or intensity of the subject's recent, present, or impending experience as being accurate when it is not.

According to the reasoning presented above, self-directed attention should minimize suggestibility phenomena in cases where the external suggestion contradicts one's internal experience. That is, increased self-focus should increase the salience of veridical internal information, thus increasing the degree to which the latter is used preferentially in determining the subsequent self-report. As the misleading external information is disregarded in favor of the internal information, the suggestibility effect should diminish.

This reasoning has received one empirical test, in a study on placebo effects (Gibbons, Carver, Scheier, & Hormuth, 1979). Subjects in that study were given a placebo and were either misinformed or correctly informed about the effects of the drug. Misinformed subjects were told that the drug would produce a slight increase in heart rate, sweaty palms, and a tightness in the chest. All subjects were subsequently asked to report the degree of arousal and the specific arousing symptoms that they were experiencing. These reports were obtained either in front of a mirror or not. Neither mirror nor no-mirror subjects reported experiencing the target symptoms when they had been correctly informed about the nature of the drug. Among

misinformed subjects, however, those not exposed to a mirror apparently were taken in by the experimental cues and reported considerable arousal. In contrast, even though the specific target symptoms used in the study could not be directly observed by looking in the mirror, misinformed subjects exposed to a mirror reported minimal arousal. Indeed, the level of drug-produced arousal reported by self-aware subjects in the misinformed condition was no different from the level of drug-produced arousal reported by subjects in the correct information condition. Thus self-attention significantly reduced the placebo effect.

This finding has important theoretical implications, which will be considered more fully below under General Discussion. The data did come from a relatively circumscribed context, however—research on reactions to placebos. Because of that finding's potential importance, it seems highly desirable to assure its generality. Gaining additional information on this question was a second aim of the present research. Therefore, in pursuing our primary objective, which was to study the effects of self-focus on accuracy of self-report of internal states, we did not simply correlate subjects' internal states with their self-reports. Instead, we approached the accuracy issue by examining the role of self-attention in two kinds of suggestibility phenomena. Accuracy, then, is defined as resistance to an attempt to misdirect by experimental suggestion. The first study made use of an emotion as an internal experience. The second study examined perceptions of taste. In both cases experimental manipulations were introduced to influence subjects' anticipations about their upcoming experiences. In both cases, we predicted that heightened self-focus would lead to increased awareness of actual internal experience and would thus lead to enhanced resistance to suggestibility.

Experiment 1

In Experiment 1 we sought to investigate suggestibility in the experience of an emotion. The design of the study was somewhat more complex than that utilized by Gibbons et al. (1979), in the following respects. First, the manipulation used by Gibbons et al. was unidirectional. Experimental subjects were always led to believe that they would be experiencing more of the relevant symptoms than they actually did experience. In contrast, the suggestibility manipulation in the present experiment was bidirectional. All subjects in the present study were exposed to stimuli—slides of nudes—which have been shown to induce a moderate degree of affect—sexual attraction (Scheier & Carver, 1977). Some of the subjects were led to believe that the stimuli would be nonarousing, and others were told that the stimuli would be highly arousing. Thus, an attempt was made to drive subjects' opinions in both directions from a baseline.

In addition, the present research assessed the effects of self-focused attention in two very different ways—a strategy that has been effectively employed previously (e.g., Carver & Scheier, in press; Scheier & Carver, 1977; Scheier, Carver, & Gibbons, in press). Like Gibbons et al. (1979), we included a manipulation of self-directed attention in Experiment 1. Thus some subjects were exposed to their own images in a mirror and others were not. Validation evidence concerning the self-focusing properties of mirror presence have been presented at length elsewhere (Carver & Scheier, 1978). Unlike the subjects of Gibbons et al., however, subjects in the present experiment were also selected on the basis of their chronic tendencies to be self-attentive.

The disposition to focus attention inward has been termed self-consciousness and is measured by the self-consciousness scale (Fenigstein, Scheier, & Buss, 1975). The scale has two major components, private and public, that are only weakly correlated (cf. Fenigstein et al., 1975). Private self-consciousness involves a focus on the more personal and covert aspects of the self. The person high in private self-consciousness is more cognizant of his beliefs, moods, and feelings. Two sample items from the private self-consciousness subscale are "I'm generally attentive to my inner feelings" and "I'm always trying to figure myself out." Public self-consciousness, in contrast, reflects an awareness of the self

as a social object. Persons high in public self-consciousness are aware of their social appearance and the impressions they make on others. Two sample items from this subscale are "I'm concerned about my style of doing things" and "I'm usually aware of my appearance." It is private self-consciousness that is of greatest relevance to present concerns. That is, our prediction was based on the reasoning that self-attentive persons would be especially aware of their veridical emotional experiences. Private self-consciousness involves precisely these types of process: awareness of one's thoughts, feelings, and other internal aspects of self. Consequently, subjects were selected on the basis of private self-consciousness rather than public.

Both construct validity (Carver & Scheier, 1978) and discriminant validity (Carver & Glass, 1976; Turner, Scheier, Carver, & Ickes, 1978) have been established for the private self-consciousness subscale. Moreover, private self-consciousness as a disposition was intended to be similar conceptually to the manipulated state of self-awareness. The fact that on a number of occasions the two have led to empirically similar results indicates that they do converge on a single psychological entity (see e.g., Buss & Scheier, 1976; Carver & Scheier, 1978; Scheier, 1976; Scheier et al., 1978; Scheier & Carver, 1977). In brief, the parallel between manipulated self-awareness and private self-consciousness now seems well documented, and we expected similar results for the two variables in the present research as well. Thus self-focused attention was expected to lessen susceptibility to suggestion, regardless of whether self-focused attention was experimentally heightened by exposure to a mirror or heightened by virtue of the person's propensity to be dispositionally high in private self-consciousness.

Method

Subjects

Subjects were 55 male undergraduates from the University of Miami subject pool. Six additional subjects were deleted prior to data analysis because during debriefing they spontaneously reported the belief that the experimenter had been trying to influence their perceptions of the stimuli. Participation in the research was limited to males because the study used stimuli that had already proven to be somewhat arousing to males under relatively similar circumstances (Scheier & Carver, 1977), whereas we had no comparable knowledge of females' responses to the stimuli. Subjects, tested individually, were randomly assigned to one of the four experimental treatments described below.

Subjects were also divided into groups high and low in private self-consciousness based on their responses to items of the self-consciousness scale (Fenigstein et al., 1975), which had been administered in large group sessions several weeks prior to the study. Subjects were classified as being high in private self-consciousness if their scores fell above the median ($Mdn = 24.5$) of the pretest distribution and as low in private self-consciousness if their scores fell below the median.

Procedure

The procedure used in this study was adapted from that used by Scheier and Carver (1977). The experiment was portrayed as part of a larger project studying reactions to sexually oriented stimuli. Future subjects ostensibly would be wired with physiological recording devices to assess their bodily responses to the stimuli (photographic slides of female nudes). Before beginning that phase of the research, however, it would be necessary to evaluate and classify the stimuli that would be shown to those subjects. In particular, the experimenter continued, it was necessary to determine which slides were very arousing, which ones were minimally arousing, and so on; this was the ostensible purpose of the present sessions. The experimenter went on to explain that each participant would see only a few of the slides, however, in order to prevent overexposure to the stimuli on the part of any of the raters.

The subject was told that he would be viewing each slide twice. The first time he was simply to view it carefully and thoroughly; the second time he was to rate each slide on a separate 15-point scale, the endpoints of which had been labeled "extremely arousing" and "totally *non*arousing." The subject was cautioned not to make his ratings as a function of relative photographic or artistic qualities. Because the research to be done later concerned physiological responses, it was emphasized that all of the present judgments should be made only according to how much of a bodily reaction the slide seemed to produce in the subject, in terms of flushing, muscle tension, slight changes in heart rate, and so forth.

Suggestibility manipulation. After ascertaining that the subject had understood the instructions, the experimenter stood up to start the slide projector. As he did so, he delivered one of the following two statements in an offhanded manner. These statements constituted the instructional set or suggestibility manipulation. To subjects in the nonarousal condi-

tion the experimenter said, "By the way, you might as well know before you even start that the guys we've run so far with this particular set of slides have been reporting that they really aren't arousing at all—I mean, not at all. I've noticed that they've generally been circling points way over there on the left side of the page." To subjects in the high arousal condition the experimenter said "Well, it looks like you're one of the lucky ones. The guys we've run so far with this set of slides have been reporting that they're really pretty arousing. I've noticed that they've generally been circling points way over here on the right side of the page."

Despite these comments on the part of the experimenter, all subjects subsequently viewed precisely the same set of 7 slides. These slides had been selected from a larger group on the basis of pilot data indicating that these slides were all moderately arousing—i.e., that unmanipulated ratings of the slides fell approximately in the middle of the scales used in the main study. Thus both instructional sets constituted manipulations away from what should have been the slides' true effects on the subjects.

After delivering his remark, the experimenter started the slide projector, which automatically displayed each stimulus for 15 seconds, separated by 15-second interstimulus intervals in which no light was projected. After a 30-second interval, the cycle was repeated. During the projection period the experimenter looked away from the subject and said nothing except to inform the subject that he should make his ratings now, as the second cycle was about to begin.

Self-awareness manipulation. The slides were rear-projected onto a freestanding device that stood approximately 1 m in front of the subject's chair. This device was fitted with one of two screens (.5 m × .75 m), which constituted the manipulation of self-attention (cf. Neumann, Carver, & Scheier, 1977).[1] One, used in the no mirror condition, consisted of ordinary rear-projection material. The other, used in the mirror condition, was constructed of 50% transmission – 50% reflection glass, backed by tracing paper. The optical characteristics of the latter screen were such that when a slide was being projected, the subject could see only the slide, but during the interstimulus intervals the subject saw a reflected image of himself. Thus self-attention was enhanced during the slide series, but in such a way that the subject was not distracted from the slides. Following presentation of the slides, the subject was probed for suspicions about the suggestibility manipulation, debriefed as to the purpose of that manipulation, and dismissed.

Results and Discussion

The dependent measure was the subject's summed ratings of the arousal produced by the seven stimulus slides (see Table 1). An analysis of variance of these data revealed, as one might expect, a large main effect for instructional set, $F(1, 47) = 79.83$, $p < .001$. Subjects who expected the slides to be nonarousing reported being less aroused by them ($M = 42.74$) than subjects who expected the slides to be arousing ($M = 74.35$). Thus the expectancy manipulation seemed to have been effective.[2] Of greater interest, however, was the significant interaction between this suggestibility manipulation and mirror-manipulated self-awareness, $F(1, 47) = 4.33$, $p < .05$, of the expected form. Within both set conditions, the presence of a mirror led the slides to be rated more moderately. In short, mirror condition subjects were misled to a lesser degree by the experimenter's suggestions than were subjects in the no mirror condition. As indicated in Table 1, the strength of the mirror's influence on subjects' ratings was relatively equivalent across the two instructional set conditions. Thus, although the interaction term of the analysis of variance was significant, neither simple effect of the mirror was significant by itself.

Table 1
Mean Arousal Totals as a Function of Experimental Treatment (Combined Across Levels of Self-Consciousness), Experiment 1

Instruction	No mirror	Mirror
High arousal	78.69[a]	70.00[a]
Nonarousal	39.85[a]	45.63[b]

Note. The higher the number, the higher the arousal ratings.
[a] $n = 13$.
[b] $n = 16$.

The effects of private self-consciousness were similar in form to the effects of the

[1] Practical considerations made it impossible to prevent the experimenter from knowing which screen was in front of the subject. However, the experimenter did not know the purpose served by the different screens or the predictions being tested in the study.

[2] We had extensively pretested the expectancy manipulation in a pilot experiment, and the results of this pilot experiment showed that the manipulation was quite effective. It was for this reason that no expectancy manipulation check was obtained in either of the main experiments reported above.

mirror, but weaker. Thus, although the private self-consciousness group means were ordered in the expected direction in three of the four cases (in the fourth case the means were the same), the differences were smaller than those produced by the mirror, and no effect involving private self-consciousness reached an acceptable level of statistical significance.[3]

In part because of the weakness of the self-consciousness effect in Experiment 1, we sought to reexamine the effect of private self-consciousness on suggestibility, using a slightly different experimental setting and a more sensitive dependent measure. In Experiment 2, subjects' expectancies about a flavor intensity were experimentally manipulated prior to tasting a solution. Some subjects expected the solution to be strong, and others expected it to be weak. In contrast to Experiment 1, however, each subject in Experiment 2 served as his or her own control. This was done by individually adjusting each subject's rating of flavor intensity from his or her previously established baseline. It was predicted that subjects high in private self-consciousness would be less susceptible to suggestion than would subjects low in private self-consciousness, and would thus be less swayed by the information provided by the experimenter.

There was a second, more important, reason for conducting a second experiment. We have argued that self-focused attention makes a person more aware of his actual internal state and that the heightened salience of the person's internal state makes him less susceptible to influence. Although the findings from Experiment 1 were consistent with this reasoning, they provide only indirect evidence for our hypothesis. That is, no independent evidence was gathered that conclusively showed self-focused subjects to be more aware of their true internal state. We can only infer that they were, based on their reduced susceptibility to the bogus information provided by the experimenter. A similar criticism can be leveled against the earlier research conducted by Gibbons et al. (1979).

A second purpose of Experiment 2 was to provide a more direct test of our reasoning. Thus, in addition to manipulating subjects' expectancies about the flavor intensity they would be tasting, we also varied the actual intensity of the solution. Some subjects tasted a relatively strong solution, and others tasted a solution that was relatively weak. If self-focused attention reduces susceptibility to suggestion because it makes persons more aware of their actual internal states, then ratings of the actual intensity of the solution should be more veridical among persons whose attention is self-focused. Thus a second prediction of this study was that persons high in private self-consciousness would provide more accurate ratings of the actual intensity of the solution than persons lower in private self-consciousness.

Experiment 2

Method

Subjects

Three months prior to the experiment, several hundred undergraduate men and women at Carnegie-Mellon University completed the self-consciousness scale (Fenigstein et al., 1975). The private self-consciousness subscale was used to select subjects. Subjects were divided at the pretest median ($Mdn = 26.1$) into those high and those low in private self-consciousness.

A total of 43 men and 31 women participated in the study. Two men were dropped from the final data analysis: 1 because of suspicion and 1 because he failed to follow instructions. Within levels of self-consciousness, subjects were randomly assigned individually to one of the four treatment conditions described below, with the restriction that there be at least 8 subjects per group (cell *n*s varied from 8 to

[3] In order to determine whether public self-consciousness affected the subjects' ratings, subjects were redivided into eight new groups, based on a median split of the public self-consciousness subscale. A 2 (High vs. Low Public) × 2 (Arousal vs. Nonarousal Instructions) × 2 (Mirror vs. No Mirror) analysis of variance was performed on the data from these reconstituted groups. The results of this analysis revealed the same significant effects reported above. In addition, the main effect for public self-consciousness was also significant, $F(1, 47) = 4.36$, $p < .05$, such that subjects high in public self-consciousness reported being more aroused by the slides than did subjects low in public self-consciousness. No other significant effects were obtained.

10). As in Experiment 1, the experimenter remained blind with respect to the subject's self-consciousness score until after all data had been obtained.

Procedure

The experimenter, who was attired in a white laboratory coat, described the study as part of a larger physiological research project investigating an assortment of variables that influence bodily sensations. The present study ostensibly examined the effect of several of these variables on the experience of taste. After these brief introductory remarks, the subject was told that he/she would be tasting a number of different flavored solutions during the experimental session.

At this point, the experimental procedure was explained. The subject was asked to stand in front of a table, which was located next to a sink. On the table was a tray containing 10 small paper cups with a green colored solution in each. The cups were arranged in two rows. The first row was marked *sample* and contained four cups. The second row contained six cups and was labeled *test*. The subject was told that his/her primary task was to rate the intensity of the six flavoring agents in the test row. In order to acquaint the subject with the experimental procedure, however, he/she was being asked to rate the intensity of the four sample solutions first. In fact, only the first two sample solutions were ever rated. Intensity ratings were made along an 11-point scale, with the end points labeled "extremely weak" and "extremely strong." Inasmuch as the subject needed to have his/her hands free to handle the solutions, the intensity rating scale was posted on the wall in front of the subject so that he/she could make his/her rating verbally. Each rating was recorded by the experimenter.

The experimenter went on to explain that it was important that each person hold the flavoring agents in his/her mouth for the same length of time. Consequently, the experimenter would tell the subject when to put the solution in his/her mouth, how long to hold it there, and when to make the rating. The subjects held the solution in their mouths for 10 seconds before spitting it into the sink. They then waited 10 more seconds before making the intensity rating. The waiting period was to be used by the subject to think about the sensation produced by the solution. Once the rating was made, the subjects rinsed their mouths with water, waited for 60 seconds, and then began the next trial.

The first solution, which consisted of 1.4 parts peppermint extract mixed with 100 parts water, was the same for each subject. The second solution tasted by the subject also consisted of a mixture of peppermint extract and water but, depending upon treatment condition, was either stronger or weaker than the first solution. In the strong-solution condition, the subject tasted a solution consisting of 1.9 parts peppermint extract to 100 parts water. In the weak condition, the solution consisted of .9 parts peppermint extract to 100 parts water. The remaining eight solutions contained only water. Green food coloring had been added to all 10 solutions in order to make them similar in appearance.

In addition to manipulating the actual intensity of the second solution, the subject's expectancy about the intensity of the second solution was also varied. As the subject reached for the second solution, the experimenter casually remarked, "the second solution should be a little stronger (weaker) than the first." Thus, depending upon experimental condition, the subject expected the second solution to be either stronger or weaker than the first one he/she tasted. After the second solution was rated, the subject was probed for suspicion and debriefed.

The procedure required that each subject taste and rate the same first solution. This procedure was instituted so that the subject's rating of the first solution might be used as an anchor to which his/her second rating might be compared. Thus, an intensity change score was derived for each subject by subtracting his/her rating of the first solution from his/her rating of the second. This intensity change score constituted the primary dependent measure. A positive intensity score indicates that the second solution was rated as stronger than the first; a negative score indicated the opposite.

Results and Discussion

Private Self-Consciousness

A 2 (Strong vs. Weak Solution) × 2 (Strong vs. Weak Taste Expectancy) × 2 (High Private vs. Low Private Self-conscious) analysis of variance of the change scores revealed a significant main effect for solution, $F(1, 64) = 33.11$, $p < .0001$.[4] As might be expected, subjects who received a strong second solution rated it higher in intensity ($M = 1.09$) than subjects who received a weak second solution ($M = -.093$). There was also a significant main effect for the expectancy variable, $F(1, 64) = 11.75$, $p < .002$. Subjects who expected a strong second solution rated the second solution as being more intense ($M = .68$) than subjects who expected a weak second solution ($M = -.052$).

[4] Preliminary analyses of the intensity change scores revealed only negligible effects for the gender of the subject. The main effect for gender was nonsignificant, as were all the interactions in which gender was involved. Consequently, gender was dropped as a variable in the design, and the data from men and women were combined for all analyses reported above.

Of greater importance, however, was the significant Expectancy × Private Self-Consciousness interaction, $F(1, 64) = 4.15$, $p < .05$. Consistent with the findings of Experiment 1 and as predicted, subjects low in private self-consciousness were more affected by the expectancy manipulation than were subjects high in private self-consciousness (see Figure 1). The former group rated the second solution as being more intense when a strong solution was expected, and the second solution as less intense when a weak solution was expected, than did subjects higher in private self-consciousness.

There was also a marginally significant Solution × Self-Consciousness interaction, $F(1, 64) = p < .16$. As can be seen in Table 2, the form of this interaction was exactly opposite to that of the Expectancy × Self-Consciousness interaction. Whereas subjects high in private self-consciousness were *less* sensitive to the expectancy manipulation, they tended to be *more* sensitive to the actual intensity of the solution. As predicted, they tended to rate the strong solution as being stronger and the weak solution as being weaker than did subjects low in private self-consciousness.

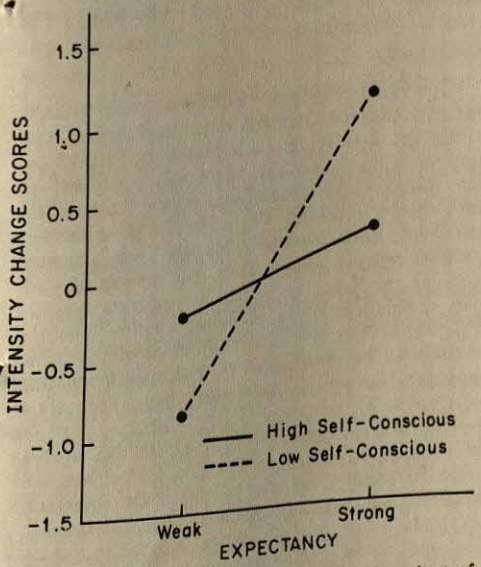

Figure 1. Intensity change scores as a function of private self-consciousness and subject's expectancy, Experiment 2.

Table 2
Intensity Change Scores as a Function of Private Self-Consciousness and Solution Intensity, Experiment 2

Self-consciousness	Weak solution	Strong solution
High private	−1.25	1.26
Low private	− .60	.91

We expected that subjects high in private self-consciousness would be more accurate in rating the actual intensity of the solution than subjects low in private self-consciousness. The form of the Solution × Self-Consciousness interaction was consistent with this hypothesis, but the interaction failed to reach an acceptable level of statistical significance. It is important to note, however, that the Solution × Self-consciousness interaction may not have been the most appropriate test of the accuracy hypothesis. For half the subjects in the study, no conflict existed between their expectancies and the actual intensity of the solution they tasted. In the absence of conflict, subjects high and subjects low in private self-consciousness should have been equally accurate in their ratings of flavor intensity. Only when the subject's expectancy conflicted with his or her actual experience should private self-consciousness have made a difference in the subject's ratings. The high group, whose judgments were presumably based on their actual internal states, should have been very accurate in their assessment of flavor intensity under conflict conditions, whereas the low group, whose judgments were based less on their internal states, should have been misled more by the experimenter's suggestions.

Given these considerations, a slightly different analysis of the intensity change scores was performed. Specifically, subjects were first separated into those who experienced conflict and those who did not experience conflict between expectancy and solution intensity. High and low private self-conscious subjects were then classified into those who were accurate in their ratings of flavor intensity and those who were not. A subject was classified as accurate if the sign of his or her

Table 3
Number of Persons Making Accurate Flavor Intensity Ratings as a Function of Private Self-Consciousness and Presence or Absence of Conflict Between Expectancy and Actual Solution Intensity, Experiment 2

	Conflict absent		Conflict present	
Self-consciousness	Accurate	Inaccurate	Accurate	Inaccurate
High private	12	4	12	5
Low private	17	2	5	15

intensity change score was in the same direction as the actual intensity of the second solution tasted. Thus a subject was classified as accurate if he or she rated the second solution as being weaker than the first and it was in fact weaker, or if he or she rated the second solution as being stronger than the first and it was in fact stronger. A subject was classified as inaccurate either if his or her change score was zero (i.e., if the subject failed to report a change in flavor intensity when one in fact occurred) or if the sign of his or her change score was opposite in direction to the actual intensity of the second solution tasted.

The results of this analysis are presented in Table 3. As can be seen from the left half of this table, when there was not conflict between expectancy and solution intensity, the accuracy of flavor ratings was high for both subjects high and subjects low in private self-consciousness. The difference between the two groups was trivial and nonsignificant, $\chi^2 < 1.0$. A very different pattern of results emerged, however, when accuracy was examined among only those subjects for whom a conflict existed between expectancy and solution intensity. As can be seen from the right half of Table 3, subjects high in private self-consciousness were still quite veridical in their assessment of flavor intensity. Of the 17 subjects high in private self-consciousness for whom conflict existed, 12 rated the intensity of the second solution accurately, and 5 rated it inaccurately. In contrast, of the 20 subjects low in low private self-consciousness who were in conflict, only 5 rated the flavor intensity accurately. This difference in the accuracy of the intensity ratings made by subjects high and low in private self-consciousness who were in conflict was highly significant, $\chi^2(1) = 5.96$, $p < .02$.[5] These findings strongly suggest that high private self-conscious persons are in fact more cognizant of their actual internal states than low private self-conscious persons, as predicted. Moreover, these findings also lend credence to the contention that it is precisely such differences in awareness of internal states between people who are high and people who are low in private self-consciousness that accounts for the differences between them in susceptibility to suggestion.

It should be noted that our purpose in conducting the present research was to document the fact that self-attentive persons are less susceptible to suggestion than persons whose attention is not self-focused, and the findings from both experiments offer strong evidence that this is indeed the case. It is

[5] The above analyses tested the accuracy hypothesis by using nonparametric statistics. However, two 2(High vs. Low Private) × 2(Strong vs. Weak Solution) analyses of variance were also performed on the raw intensity change scores—one analysis for each conflict condition. The results of these analyses paralleled those obtained for the nonparametric analyses reported above. Thus, the analysis of variance of the data for no conflict subjects revealed only a significant main effect for solution intensity, $F(1, 31) = 46.09$, $p < .001$. Subjects rated the strong solution as being stronger than the weak solution, regardless of whether they were high, $F(1, 31) = 18.37$, $p < .01$, or low, $F(1, 31) = 28.22$, $p < .01$, in private self-consciousness. In contrast, the analysis of variance performed on the data for subjects who were in conflict revealed a significant interaction between self-consciousness and solution intensity, $F(1, 33) = 5.61$, $p < .03$. When in conflict, subjects high in private self-consciousness still rated the strong solution as being stronger than the weak solution, $F(1, 33) = 6.77$, $p < .02$, but those low in private self-consciousness did not, $F < 1.0$.

also true, however, that self-attention did not entirely eliminate suggestibility effects. That is, even self-aware subjects in Experiment 1 differed in their ratings of the stimulus slides as a function of the arousal instructions (see Table 1), and even high private self-conscious subjects in Experiment 2 differed in their ratings of solution intensity as a function of the expectancy manipulation (see Figure 1). What is important, though, is that self-attentive subjects were significantly less susceptible to both of these manipulations than were subjects who were less self-attentive.

Subsidiary Analysis

In order to determine the effect of public self-consciousness on intensity ratings, subjects were redivided into eight new groups, based on a median split of the public self-consciousness subscale. A 2 (High vs. Low Public) × 2 (Strong vs. Weak Solution) × 2 (Strong vs. Weak Taste Expectancy) was then performed on the intensity changes scores. The previously mentioned main effect for solution was still significant, $F(1, 64) = 29.81$, $p < .001$, as was the main effect for the expectancy variable, $F(1, 64) = 13.38$, $p < .001$. Neither the main effect for public self-consciousness, $F(1, 64) = 2.46$, $p < .05$, nor any interactions involving public self-consciousness were significant. Thus, the effects of public self-consciousness in Experiment 2 were negligible.

General Discussion

Experimental Findings

The idea that attention plays an important role in the perception of bodily states is not a new one. Schachter and Rodin (1974), for example, have discussed the importance of this variable in their obesity research, drawing a distinction between internal and external personality types. They point out that "externals" tend to rely upon external cues for information about their internal states, whereas "internals" respond more to internal cues and appear to be more in touch with their actual bodily states. The present research takes this notion a step farther, however. The results of both studies appear to indicate that self-attention can lead to heightened awareness of internal experience even when the experience directly contradicts experimentally induced expectancies.

Moreover, the greater accuracy of self-report that comes with increased attention is not limited to reports of bodily states. That is, previous research has shown that self-reports of behavioral tendencies are most accurate when obtained under conditions of experimentally heightened self-awareness (Pryor et al., 1977). Similarly, persons high in private self-consciousness have been shown to provide more veridical self-reports of their behavioral tendencies than do persons lower in private self-consciousness (Scheier et al., 1978). In brief, self-directed attention appears to be an important determinant of the extent to which a person is aware of his or her bodily states, attitudes, and dispositions. As such, it is also an important determinant of the accuracy with which those states, attitudes, and dispositions are reported.

Related Suggestibility Findings

We have shown in the present research that self-focused attention can heighten a person's cognizance of his or her internal state and thereby make that person *more* resistant to the suggestions and influence of others. In contrast, previous research has shown that heightened self-focus can also lead a person to be *less* resistant to the influence of others and more likely to conform (Carver, 1974; Duval, 1976; Wicklund & Duval, 1971). For example, Wicklund and Duval (1971) found that subjects who listened to their own voices on a tape recorder conformed more with the modal opinion of a positive reference group than did subjects who listened to the tape-recorded voice of another person.

There are at least two ways, however, in which these previous studies differ from the present research, and these differences between the two sets of studies may account for the different sets of findings. The first difference involves the specific self-aspect toward which the influence attempt was di-

rected. Our own research and the earlier research by Gibbons et al. (1979) attempted to influence the person's belief about his or her internal bodily state. This research uniformly showed greater resistance to suggestion as a function of increased self-focus. In contrast, the earlier research showing decreased resistance to suggestion either attempted to influence the person's opinions, beliefs, or standing on some attitude topic (Wicklund & Duval, 1971, Experiment 1) or attempted to influence his or her assessment of an ambiguous external stimulus (Duval, 1976).

Thus, in each of these earlier studies, an attempt was made to influence the person's opinion about some aspect of self (attitudes or beliefs) or some aspect of the external environment (an ambiguous stimulus) for which there was no clear right or wrong position. That is, in each case the correctness of the person's position required extensive social validation (cf. Festinger, 1954). In contrast, the correctness of one's perceptions of one's own bodily states may require less social validation. Persons have direct access to information that enables them to determine for themselves whether they are aroused or not, whether something tastes strong or weak, and so on.[6] In brief, we suggest that important differences exist in the extent to which a person's judgments about himself or herself require social validation. For some self-aspects, like bodily states, little social validation may be necessary, and it may be for only those self-aspects, like bodily-states, that self-focused attention will increase resistance to suggestion.

A second possible difference between the two sets of studies rests on the distinction that has been drawn between private and public self-consciousness. Although the private–public distinction has so far been applied solely to individual differences in self-consciousness, only a small extrapolation is needed to apply the distinction to manipulations of self-awareness as well. Indeed, Buss (in press) has already suggested that self-awareness manipulations might be usefully categorized in terms of whether or not they are likely to induce awareness of the private or public aspects of self. He argues, for example, that exposure to a mirror is likely to induce private self-awareness, and the parallels that have been obtained between the mirror and private self-consciousness would seem to substantiate this claim (see e.g., Carver & Scheier, 1978; Scheier, 1976; Scheier & Carver, 1977). On the other hand, a variety of manipulations might induce public self-awareness and make the person more cognizant of himself as a social object. Examples of manipulations that might fall into this category are exposure to an audience, exposure to a TV camera, and hearing one's own tape-recorded voice.

Although the effect of public self-consciousness in the present research was negligible, it should be remembered that we attempted to influence the person's perception of his or her bodily state. The fact that public self-consciousness had little effect in this circumstance is not necessarily unexpected. That is, perhaps public self-consciousness is relevant to suggestibility only when the influence attempt involves self-aspects that require more extensive social validation. In this regard, it is interesting to note that virtually all of the earlier research in which self-focused attention increased suggestibility used manipulations that might have heightened public self-awareness—for example, the person's tape-recorded voice (Wicklund & Duval, 1971) and a TV camera (Duval, 1976). In addition, the influence attempts in those studies were aimed at self-dimensions that typically required validation from others—an attitude (Wicklund & Duval, 1971) and an ambiguous judgment (Duval, 1976). Thus, the manipulations used in those studies may have increased

---

[6] It should be noted that these comments about social validation and ambiguity are meant *only* to apply to the person's ability to identify in himself the presence or absence of a particular physiological state—e.g., identifying the presence or absence of arousal. They are not meant to apply to the person's ability to provide a name for his state—e.g., labeling the arousal as fear (cf. Schachter & Singer, 1962). Nor are they meant to apply to the person's ability to identify the source or cause of his state—e.g., knowing that the arousal was produced by running (cf. Zillman, Johnson, & Day, 1974).

the person's awareness of self as a social object, with a concomitant increase in concern over the appraisal and evaluations of others, in contexts where others' opinions are needed to evaluate one's own position. If so, the fact that these earlier studies found increased suggestibility due to heightened self-focus becomes less surprising.

Theoretical Implications

As was noted earlier in this article, the finding that self-directed attention can weaken suggestibility phenomena has important theoretical implications. These implications concern two alternative interpretations that might be invoked to explain findings of previous research in which mirrors were used as manipulators of self-focus. One of those interpretations is based on drive theory, the other on the notion of experimental demand.

In its simplest form, a drive-theory interpretation of mirror effects holds that the presence of a mirror leads to heightened drive or arousal, which in turn causes dominant responses to be emitted with increased frequency. Thus subjects' behavior is more in line with salient behavioral standards when a mirror is present than when it is absent (cf. Liebling, Seiler, & Shaver, 1974). The second potential explanation of the effect of a mirror is that it makes subjects more sensitive to demand characteristics (Orne, 1962) that are inherent in the experimental situation. According to this argument, subjects in the presence of a mirror do what they think the experimenter wants them to do to a greater degree than do subjects with no mirror.

Although either of these two explanations might provide an adequate account for some previous mirror-induced effects (e.g., Carver, 1974, 1975; Gibbons, 1978; Scheier, Fenigstein, & Buss, 1974), there are a number of other findings that neither approach can explain (e.g., Duval & Wicklund, 1973; Gibbons, et al., 1979; Carver & Scheier, Note 1). Nor can they account for the present findings. If a mirror increases arousal, all of the subjects in the present Experiment 1 who responded in the presence of a mirror should have experienced—and thus reported—more arousal than those with no mirror. Instead, the mirror manipulation interacted with the bogus information provided the subjects. Alternatively, if a mirror increases the emission of dominant responses, the interaction should have taken a form opposite to that which did occur, as subjects emitted the responses that had been rendered dominant by the experimenter's suggestions. Finally, if a mirror increases responsivity to experimenter demand, then self-aware subjects in the present research should have been more influenced by the experimenter's comments. The fact that they were less swayed by the suggestions of the experimenter than were less self-attentive subjects renders a demand-based interpretation of the present and previous findings much less tenable.

It is also worth noting that any attempt to apply drive or demand interpretations to mirror effects seemingly implies that such interpretations should be applicable to self-consciousness effects as well. The self-consciousness scale, however, has been found to be unrelated to measures of test anxiety, social anxiety, achievement motivation, general emotionality, impulsivity, intelligence, and social desirability (Carver & Glass, 1976; Turner et al., 1978). Drive or demand interpretations of self-consciousness effects would seem to require that some of these correlations be positive. In brief, the most viable interpretation of the accumulated research involving both manipulated self-awareness and dispositional self-consciousness appears to be based on attention. It is the only explanation that can simultaneously account for the effects of each of these variables, and it is the only explanation that can account for the entire set of findings.

tive support for age-related changes regarding some of the levels (a Levels × Populations interaction), although their results are open to alternative interpretations.

Perhaps the most fundamental criticism relates to the adequacy of the stories used. First, there is doubt as to whether at least some of the stories reflect the criteria that they are intended to represent, especially at the foreseeability level (Sedlak, 1978). Second, factors such as effort that have been shown to affect AR (Raymond & Dillehay, Note 1) are confounded with the attribution criteria. Third, each level is presented in different situational contexts, a variable that affects AR according to Shaw and Sulzer's (1964, p. 45) qualitative observations. The inclusion of only two stories at each level may be insufficient to prevent the confounding of level and story context. Finally, the use of the same story character is likely to increase subject reactivity. These kinds of factors possibly produced anomalous findings such as a decrease in children's AR from foreseeable (but accidental) to intentional negative outcomes. Later research in this tradition (e.g., Shaw & Reitan, 1969; Shaw & Schneider, 1969; Sulzer & Burglass, 1968) is similarly plagued by basic problems of interpretation, and even though a new more satisfactory set of Perry stories has been devised, they have to date only been used with children in a cross-cultural study (Shaw & Iwawaki, 1972).

In an attempt to meet the above criticisms, Harris (1977) used a single situation to present Heider's levels to five different age groups (7-, 9-, 12-, and 13.5-year-olds and college students). Utilizing a between-subjects design, he obtained partial support for Heider's theory. Although an Age × Stimulus Level interaction was found for the perception of causality, this interaction only approached significance ($p < .09$) for AR. Furthermore, no distinction was found between causality and foreseeability despite a successful check on the manipulation of this variable. Finally, levels of the stimulus event did not affect 9-year-olds' perceptions of naughtiness but did have an effect on adjacent age groups. No explanation is offered for this result. Perhaps the strongest support for the age-related nature of Heider's levels stems from a recent study by Sedlak (1979). Despite an exceptionally small sample, she showed via multidimensional scaling that 8-year-olds, 11-year-olds, and adults utilized Heiderian criteria as a dimension in their cognitive representations of stimulus stories. Moreover, the salience of this dimension (relative weighting) was directly related to age, supporting the notion of increasing AR differentiation with development. However, even adults did not distinguish Heider's last two levels of intentionality and justifiability, thus replicating Shaw and Sulzer's (1964) earlier results. It thus appears that although previous research is adequate for testing aspects of Heider's (1958) ideas, the relevant attribution criteria have not been adequately operationalized, nor have developmental differences in AR been fully investigated. For example, the implicit assumption that AR is cumulative because higher levels imply lower levels of attribution (e.g., perceived intentionality implies perceived foreseeability, causality, etc.) has never been evaluated. Consequently, the status of Heider's last two levels (intentionality and justifiability) is unclear, and it is not known whether age differences in AR actually reflect developmental stages.

One aspect of Heider's theory, the development of AR based on intention, appears to have been established by Piagetian research. Both early and recent methodologically innovative studies show that the degree to which intentional perpetrators are held responsible for outcomes increases with the age (e.g., Gutkin, 1972; Hebble, 1971). As Karniol (1978) notes, however, these studies tend to vary intentionality in the context of accidentally produced outcomes and hence are not valid tests of Heider's (1958) two levels. In contrast, some investigations have not found the traditional age shift in evaluations of intentional versus accidental acts (e.g., Armsby, 1971; Farnill, 1974; Sedlak, Thompson, & Sands, Note 2). Whatever the developmental status of intention information utilization, this literature is clearly limited to testing only a single aspect of Heider's theory.

Research in Heiderian and Piagetian traditions displays several common features. In both attempts to understand, developing no-

tions of AR occur via the child's evaluation of another's actions. However, Piaget (1932) clearly stated that children's moral judgments of themselves and others would differ. In respect to the self, children succeed much earlier (at age 3 or 4 years) "in differentiating intentional faults from involuntary breaches of the moral code" (p. 180). A second limitation relates to the almost exlusive focus on a single attribution measure. With the exception of Harris (1977), all studies assess only moral attribution. But as Shaver (1975, p. 102) points out, attribution of causality and responsibility are not necessarily synonymous, although they are often assumed to be. Finally, attempts to obviate subject reactivity have often resulted in the use of between-subjects designs, whereas a within-subjects design is necessary for investigating the cumulative nature of Heider's AR levels.

Experimental Overview

The present study attempts to clarify certain conceptual issues and meet several of the methodological problems outlined above. Conceptually, it was considered that Heider's (1958) analysis of AR was incomplete at the highest levels. Although a facilitative cause is held to diminish responsibility (justifiability), no mention is made of a converse negative environmental force. Theoretically, such a force should, in accordance with Kelley's (1971) augmentation principle, increase responsibility, and hence a sixth level was hypothesized. In addition, it seems plausible that a more accurate developmental picture may be yielded by investigating AR in relation to the self. Consequently, negative-outcome stimulus stories representing six attribution criteria were administered to five developmental groups (6–7.5, 8–9.5, 10–11.5, 12–13.5 years, and adults) under two stimulus conditions; the actor was either a hypothetical other or the self.

Methodologically, this study differed from previous experiments in two major respects. First, a Latin square design was used to control for story context. Hence levels were varied within a single story theme. To retain the advantages of a within-subjects design (cf. Sulzer, Note 3) and in order to evaluate the scalability of Heider's levels without increasing subject reactivity, six story contexts were generated yielding 36 stimulus items. Subjects were thus presented with a different level from each of the story themes. Second, two different attribution measures were used. One required an ascription of causality, whereas the other asked for an assessment of blame.

It was hypothesized that the attribution measures would evoke two distinct attribution styles leading to different response patterns. More specifically, an interaction between age and story character (self versus other) was predicted for the moral judgment measure on the basis of Piaget's (1932) theory. Younger children were expected to evidence a difference in these two conditions, whereas older ones were not. No such interaction was predicted in regard to perceived causality. In terms of Heider's (1958) theory, it was anticipated that both attribution measures would evidence an effect for stimulus level, the subject's age, and the interaction of the two factors. Generally, younger children were expected to show a high and more global level of attribution across the stimulus levels in contrast to older subjects' differentiated attributions, which should show greater differences across the levels.

However, it was anticipated that the nature of the interaction between age and stimulus level would be different for the two attribution measures. In regard to blame, a convergence of age groups was hypothesized to occur only at the higher levels, including intentionality, whereas attribution of causality might coincide at the levels of causality or foreseeability. This prediction was based on the belief that judgment of causality is not primarily an evaluative event and may therefore result in an earlier consensus. Also, attribution of blame at the adult level should only be maximal at the highest stimulus levels, whereas the less differentiated responses of children may show such blame at lower levels.

Finally, it was held that Heider's AR model should display the characteristics of a Guttman scalogram as suggested by Fishbein

and Ajzen (1973). However, previous evidence for the developmental nature of these AR criteria is based solely on quantitative group scores and is thus open to question. No attempt has been made to look at individual response patterns in a developmental context.

Method

Subjects

Two hundred and forty persons participated in the study. Children were drawn from two Oxford schools and fell into one of four age groups determined by whether it was their second (for age, $M = 82.75$ months, $SD = 4.83$), fourth ($M = 105.55$ months, $SD = 5.05$), sixth ($M = 132.47$ months, $SD = 3.43$) or eighth ($M = 150$ months, $SD = 4.79$) year of formal education. To control for socioeconomic class, the schools selected were sited on the same council housing estate (predominantly lower middle class) within 600 m of each other. The adult group comprised both graduates and undergraduates at the University of Oxford as well as students from Oxford Polytechnic.

Equal numbers of male and female subjects were tested at each age level. The sample was almost exclusively white; only one or two black children were present in each age group.

Stimulus Stories

Stimuli comprised stories reflecting six familiar contexts (e.g., riding a bicycle) within which the attribution levels were varied. The construction of the stories followed three stages. Initially, 10 graduate students in psychology rated the stimuli on each of Heider's extended attribution criteria. On the basis of these responses, a second modified set of stories was constructed and again rated. Informal discussion following this procedure led to further but less extensive modifications. The full set of 36 stories was then presented to 6 senior PhD students in social psychology who had not participated in the previous phase. The students were asked to classify each story according to level after they had read Heider's (1958, pp. 113–114) description of the levels and the rationale for including a further stage. Because unanimity was obtained, no further structural changes were made. Finally, the stimuli were informally discussed with two teachers who were asked to comment on the linguistic complexity of the stimuli and on the children's familiarity with the words used. A few minor alterations consisting mainly of word changes were made at this stage.

Because the precise manner in which Heider's levels of responsibility are operationalized is of some importance, the structural features of each are presented below. It should be noted that an attempt was made to follow the exact general examples given by Heider:

Level 1 (association). At this level the actor was associated with the outcome in two ways; by spatial and temporal contiguity and by ownership. Typically, a victim is accidentally hurt in the actor's presence and by an object belonging to the actor.

Level 2 (causality). Here the actor merely causes the outcome. In a situation where competence can reasonably be assumed, the actor accidentally hurts a victim of whose presence he or she is not even aware (e.g., the actor slips while running).

Level 3 (foreseeability). Although the harm is still caused accidentally, foreseeability is achieved by a slight change of conditions. The actor experiences a lack of competence (e.g., the actor continually slips while running along a wet surface) and is aware of being a potential harmdoer (the actor sees the victim come and run too close to him or her.)

Level 4 (justifiability). Justifiability was represented by an "eye for an eye" situation. Hence when the actor saw someone prepare to attack him or her in some way (e.g., run past and knock the actor over while running), the actor responded to the provocation by doing to the other person exactly what would have been done to the actor as the victim.

Level 5 (intentionality). The actor behaves in the same manner as at the previous level, but there is no provocation. The actor thus appears as a free, uncoerced agent.

Level 6 ("supererogation"). This level is exactly the same as the previous one, except that the actor contravenes a request by the victim's mother to be careful "as my boy (girl) gets hurt very easily." (Notice that the order of Heider's, 1958, Levels 4 and 5 has been reversed to create a ranking of increasing internality of causation.) [1]

A characteristic common to all the stories was that they represented a realistic description of an action sequence; they only contained information that would have been available to an observer of the episode. Hence attributional criteria (e.g., intentionality) were not explicitly mentioned in any of the stories. However, an attempt was made to keep the demands made on social inference abilities at a bare minimum to avoid results that merely reflected age-related differences on this variable. A final feature of the stories was the use of only two similar outcomes. In three of the story contexts, the consequence of the actor's behavior was a bleeding nose, whereas in the other three he/she produced a bleed-

[1] Attribution of responsibility is a function of both the observers' response level and the stimulus level. Heider orders his criteria according to the former, whereas the reversal is made on the latter. The present attempt to order the levels according to increasing attribution was done to allow the possible emergence of a Guttman scale response pattern.

ing lip. These outcomes were chosen because they were judged to be of medium intensity.

Stimulus stories were combined to produce six sets of stimuli that contained one attribution level from each story context. The procedure followed is detailed in Winer (1971, p. 689). Since a Greco-Latin square design, which would have allowed assessment of any order effect in addition to the context variable, was impracticable in terms of subject number, a fixed order of presentation was followed. The exact order was randomly determined. It should be noted that any order effect should have worked against the hypotheses of the study.

Procedure

All subjects were administered one of the six stimulus story sets. To facilitate younger children's understanding of the task requirements, 6- and 8-year-olds were read the stories in small groups of 4 so that individual attention could be given to each subject. Owing to practical difficulties, all other subjects read the stories in normal class (lecture) periods (25–30 persons). An attempt was made to avoid comprehension difficulties among the older children by specifically excluding subjects known to have reading difficulties or learning problems of any sort. In addition, three adults were freely available to assist whenever any difficulty was encountered by a subject. Their help was, however, rarely required, as almost all the children found the task requirements fairly simple. A further precaution was taken in constructing the test booklets. Each story was presented on a separate page followed by the appropriate rating scale alongside which appeared a clear line drawing of the central object in the story. Any comprehension difficulties should have led to random responding and would therefore not have supported the experimental hypotheses.

Before proceeding with the task, each group was told that sincere and honest individual responses were important even though the study was concerned with group differences. Subjects were assured of complete anonymity to allay any further anxiety, and the importance of the results was emphasized. In the self–actor condition, subjects were told that they would be presented with imaginary stories about themselves and were asked to respond to the situation as if it had actually occurred. The other–actor condition stories were described as situations that had occurred, and subjects were asked to give their evaluations. Some time was spent explaining the use of the rating scales and ensuring that the concepts of blame and cause were understood. Where necessary, examples were given. It should be emphasized that both the language used and extent of elaboration given were varied as a function of the subjects' age and apparent comprehension. The latter was considered more important than adherence to a rigidly worded set of instructions. Finally, subjects were given two very explicit practice items and their correct use of the rating scale was checked by supplying appropriate feedback.

Each subject's responsibility attribution was assessed by asking, "How much should ACTOR be blamed for the boy (girl) getting hurt?" (in the experimental situation the appropriate name or pronoun was used). Subjects indicated their answers on a 7-point rating scale comprising a single empty rectangle and six Xs of increasing height. The rectangle was labeled "none," the midpoint, "medium," and the last X, "totally." The first and fifth Xs were labeled "very little" and "very much," respectively. The rectangle was used to emphasize the qualitative distinction between attributing blame and no blame, in contrast to the quantitative differences in the amount of blame assigned, represented by increasing Xs.

Subjects were then asked, "How much was ACTOR the cause of (reason for) the boy (girl) getting hurt?" Again, subjects indicated their answers by ticking an appropriate scale point. Darkened rectangles replaced the Xs in an attempt to ensure that the two questions that followed each story were answered on the appropriate scale. The order of the questions was not varied, since it was judged that the use of only two questions was unlikely to result in any fatigue or similarly distracting effects.

Results

An initial 2 (condition) × 5 (age) × 6 (level) × 2 (attribution measure) analysis of variance was conducted to determine whether separate analyses for the two dependent measures were justified. As hypothesized, a significant main effect for attribution measure, $F(1, 230) = 6.52$, $p < .05$, was found. Hence perceived blame and causality served as dependent measures in separate univariate analyses.

Because the self-versus-other as actor was hypothesized as an interaction effect, analyses for sex and story context differences were conducted on the data for each condition separately.

Sex Differences in Attribution

To test for sex differences, a 5 (age) × 6 (level) × 2 (sex) analysis of variance was carried out. In respect to both perceived blame and causality, sex produced neither a significant main effect nor an interaction in either actor condition ($p > .10$). Consequently data for both sexes were combined in subsequent analyses.

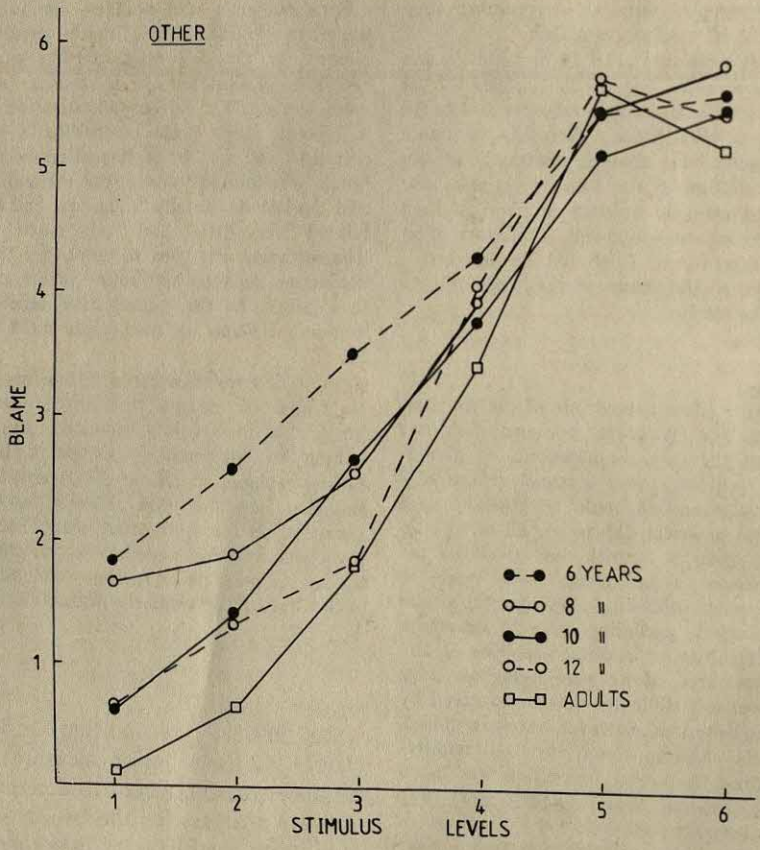

Figure 1. Mean moral attribution as a function of stimulus level for other as actor.

Story Context Effects

In evaluating possible story context effects, age was not included as a separate factor because stable differences were considered unlikely to emerge with only four subjects per cell. A 6 (story) × 6 (level) analysis of variance showed that story context did not emerge either as a main effect or in interaction across both dependent measures and administration conditions ($p > .10$). All further analyses therefore also ignored story context.

Measure of Perceived Blame

It was hypothesized that subjects' blame judgments would be affected by the subjects' age, the stimulus level, and the interaction of these two factors, whereas administration condition (self vs. other) was held to be important only at a younger age. Subjects' mean scores in both conditions are displayed in Figures 1 and 2. These data curves suggest a configuration consistent with the predicted results. An analysis of variance performed on the data revealed that the effects of subject's age, $F(1, 230) = 13.92$, $p < .001$; stimulus level, $F(5, 1150) = 396.79$, $p < .001$; the interaction of these two factors $F(20, 1150) = 4.92$, $p < .01$; and the interaction of story character with age, $F(4, 230) = 2.73$, $p < .05$, were all significant. No other significant results were found.

To further investigate the relationship between the effects of subjects' age, the stimulus level, and their interaction, simple main effects analyses of variance were computed following Kirk's (1968, pp. 284–294) recommended procedure. The results were consistent with the prediction that younger sub-

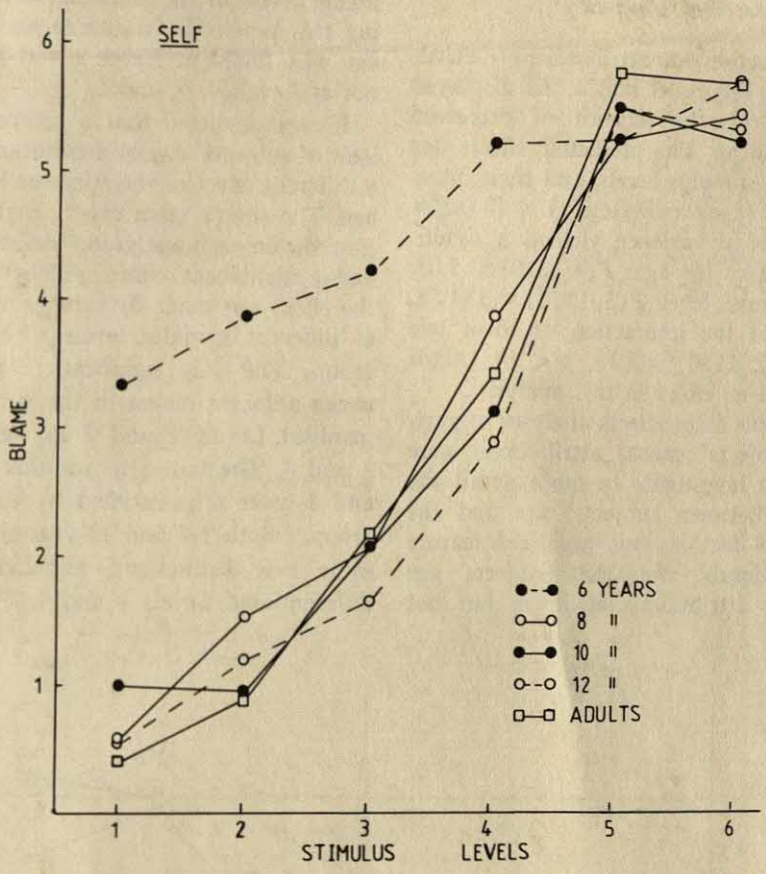

Figure 2. Mean moral attribution as a function of stimulus level for self as actor.

jects would attribute more blame at lower levels of the stimulus factor than adults. A simple main effect for age was found in all but the last two levels (in these and subsequent analyses the .01 level was adopted unless otherwise stated).

A second predicted feature of the age–stimulus level relationship related to possible differential effects of the stimulus level at various ages. The simple main effects analysis showed a significant stimulus level effect at all ages. To probe these effects in greater detail, comparisons between adjacent levels of the stimulus factor were made. The pattern of results supports the notion of increased differentiation of AR criteria with age. While 6-year-olds significantly distinguished only accidental from intentional outcomes (Levels 3 and 4), 8-year-olds in addition differentiated Levels 4 and 5. Ten-year-olds drew a further distinction in clearly separating Levels 2 and 3, an additional distinction not made by the 12-year-old group. Finally, adults clearly distinguished all levels except the first and last pairs.

A similar main effects analysis of variance was conducted to determine the exact nature of the Story Character × Age interaction. It was found that only the youngest age group was affected by actor type in their attribution of blame. Further investigation showed that this difference was manifest at the association, causality, and justifiability levels. However, the direction of the difference was opposite to that expected; greater blame was attributed in the self- than in the other condition.

Measure of Perceived Causality

The mean scores for attribution of causality appear in Figures 3 and 4. As displayed in these figures, the pattern of perceived causality confirms the predicted effects for subjects' age, stimulus levels, and their interaction. A 5 (age) × 6 (levels) × 2 (actor type) analysis of variance yielded a significant main effect for age, $F(4, 230) = 5.03$, $p < .01$; stimulus level, $F(5, 1150) = 184.51$, $p < .001$; and the interaction of these two factors, $F(20, 1150) = 3.25$, $p < .01$. Actor condition had no effect in this analysis.

Again, simple main effects analyses of variance for subjects' causal attributions were performed to investigate in more detail the relationship between subjects' age and the stimulus level factors. One predicted feature of this relationship was that subjects' age would affect attributions at lower but not higher levels of the stimulus factor. Supporting this prediction, a simple main effect for age was found at Level 2 and Level 3 but not at Levels 4, 5, and 6.

It was predicted that a second characteristic of subjects' causal attributions would be a different effect of the stimulus level at each age. The simple main effects analysis showed that within each age group the stimulus level had a significant effect. Further analysis of the effect was made by comparing the means of different stimulus levels within each age group. The only significant differences between adjacent means in the youngest group involved Levels 1 and 2 as well as Levels 3 and 4. The latter, in addition to Levels 4 and 5, were differentiated by the 8-year-old group. Both 10- and 12-year-olds made the same two distinctions, although they also differentiated Levels 1 and 2. For the adult

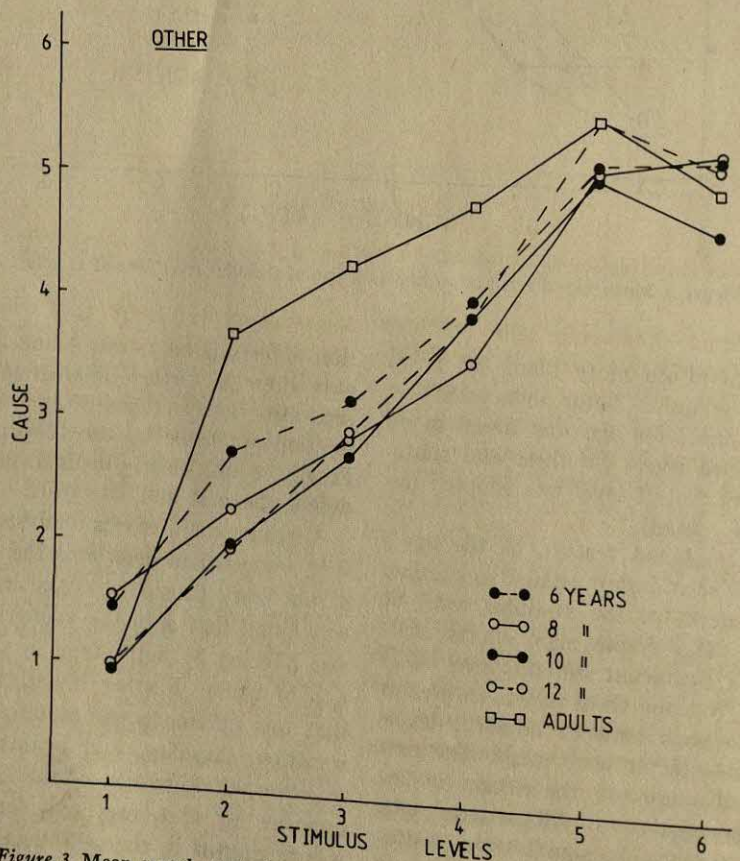

Figure 3. Mean causal attribution as a function of stimulus level for other as actor.

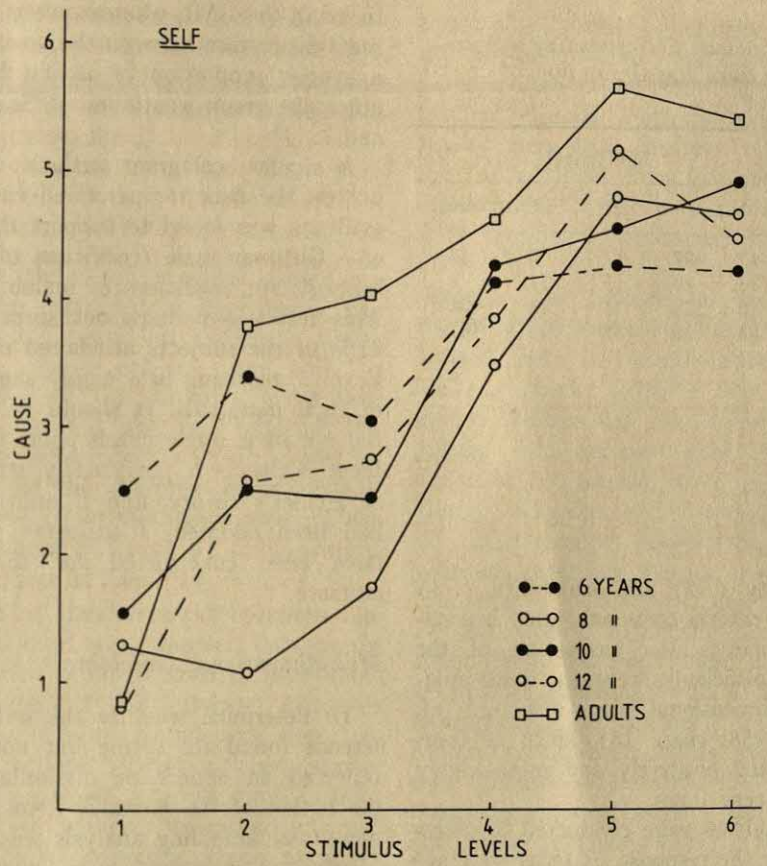

Figure 4. Mean causal attribution as a function of stimulus level for self as actor.

group, significant differences were obtained for Levels 1 and 2 and Levels 4 and 5. In sum, distinctions were mainly made between Level 1–2, 3–4, and 4–5 pairs, while no group distinguished Levels 2–3 and 5–6.

Developmental Stages in Attribution of Responsibility

A Guttman scalogram analysis was performed on the complete set of AR data gathered in the study. Although an Actor Condition × Age interaction was found, two separate analyses were not conducted for two reasons. First, the interaction obtained did not affect the order relationship between blame attributions and the various stimulus levels. Second, deterministic models for categorical data scaling tend to capitalize on chance variation, making the use of samples as small as 120 subjects a "dangerous extravagance" (Torgerson, 1958, p. 324). In addition, only Heider's original five levels were included in the analysis, since no age group distinguished Level 5 and Level 6, and only one subject attributed blame in the latter case but not the former.

An initial scalogram analysis showed that Heider's levels displayed the expected ordering but also revealed that the distribution of responses at Level 5 was skewed beyond an acceptable level. Because this is one of the auxiliary criteria that can lead to a spuriously high coefficient of reproducibility, this statistic was recalculated on the basis of Levels 1 to 4 data only (Level 5 was, however, still retained in order to distinguish the 13.3% of scale types who attributed blame at this level but not at the previous stimulus levels). The coefficient of both

Table 1
Percentage of Subjects Corresponding to Pure Scale Types in Each Age Group for Perceived Blame

Scale type	Age (years)				
	6[a]	8[b]	10[c]	12[d]	Adult[e]
5	47	27	12	8	3
4	13	10	15	14	8
3	10	23	25	22	31
2	24	25	38	42	47
1	3	12	10	14	11
0	3	3	0	0	0

[a] $n = 38$.
[b] $n = 40$.
[c] $n = 40$.
[d] $n = 36$.
[e] $n = 38$.

reproductibility (.92) and scalability (.73) exceeded the criteria commonly used in evaluating Guttman scales. Inspection of the correlation coefficients between items suggested a unidimensional latent structure (cf. Torgerson, 1958, chap. 13), since adjacent items correlated positively and more highly than nonadjacent items.

Further analyses were conducted to determine whether the response patterns were age related. The scale scores, based on all five Heiderian levels, differed in the expected manner; they were inversely related to age, $F(4, 235) = 6.32$, $p < .01$. However, multiple-means comparisons showed that the four oldest age groups did not significantly differ from each other, although they all differed from the youngest group. Table 1 shows the age distribution of the 86.25% of responses conforming to perfect scale types. From the data displayed in this table it can be seen that the age effect may possibly derive from younger subjects' dominance at Scale Type 5. This tendency is in part due to bias introduced by the self-as-actor manipulation, and hence scale scores for the other-as-actor condition were analyzed. No significant effect for age was found, $F(4, 115) = 1.58$, $p > .10$. Moreover, inspection of the age-by-scale-type distribution for this data showed no strongly discriminable age-related pattern except that (a) some younger children were undifferentiated in their AR, whereas every adult made some distinction between the levels; and (b) a greater proportion of adults than of any other age group was found at Scale Types 2 and 3.

A similar scalogram analysis was carried out on the data for perceived causality. No evidence was found to support the existence of a Guttman scale (coefficient of reproducibility $< .90$; coefficient of scalability $< .60$). This result is perhaps not surprising, since 81% of the subjects attributed causality by Level 2, resulting in a highly skewed spread of item marginals. It should be noted that the use of a single cutoff point for building these scales is a particularly stringent test of Heider's theory, and if multiple criteria had been adopted, a scalogram might also have been constructed for the causality measure.

Multidimensional Unfolding

To determine whether the self/other difference found for blame but not for cause reflected an underlying dissimilarity in the perception of the stimulus items, a multidimensional unfolding analysis was attempted. Degenerate solutions were repeatedly obtained owing to a lack of constraint in the data. To increase response variability, adult and child data were combined, but again, unstable solutions emerged. Inspection of the raw data showed that there was much consensus in the response patterns across the various ages (e.g., no subject showed a systematic decrease in AR with increasing level), and hence this analysis was abandoned.

Attribution to Intentional Versus Unintentional Behavior

In terms of Piaget's (1932) theory, the major moral development in middle childhood involves a shift from outcome-based to intention-based judgments. Comparisons were thus made between Level 2 (an uncoerced unintentional act) and Level 5 (an uncoerced intentional act) to determine whether subjects differentiated intentional from unintentional events in their attributions. These comparisons were made for both attribution

measures and within each age group. Significant differences were found on both variables for all the groups ($p < .05$), indicating an emergence of this change earlier than is traditionally expected.

Discussion

In general the results provided strong support for the experimental hypotheses. For both moral and causal attributions a strong interaction between subjects' age and the characteristics of the stimulus event was found. As predicted, the data reflected significant age differences in mean scores at lower levels of the stimulus factor but not at higher levels (for the moral measure the convergence was at Level 5; for perceived causality, it was at Level 4).

The form of the interaction between age and stimulus level was, however, only partly consistent with a developmental interpretation of Heider's (1958) theory. Although increasing age was associated with more significant distinctions between adjacent stimulus levels, this result requires some qualification. Almost without exception all age groups attributed increasing blame as actor behavior became more internally directed. Hence even the youngest children appeared on the average to show distinctions in the hypothesized direction between Heider's criteria for AR. With development these distinctions became more marked. Sedlak's (Sedlak, 1979) finding with respect to the age-related importance of Heider's criteria in cognitive representations directly supports the present results.

In addition to the above, it was found that even the 8-year-old group distinguished between intentionality and justifiability, the second significant differentiation to emerge with age. This contrasts with Shaw and Sulzer's (1964) study, where only adults made a slight distinction between these two criteria, leading to the suggestion that they may only be fully appreciated by "mature" senior citizens. The early emergence of this sophisticated attribution process is perhaps not surprising for three reasons. First, the justifiability level was operationalized in terms of a familiar, commonly occurring situation for children (self-defense), whereas parents often model AR judgments on justification. Second, outcome valence and intensity were held constant within the context of a single story presentation. Third, development of AR may be fairly rapid in such familiar interpersonal situations with undesirable outcomes; casual observation suggests that explanations are more often sought after something bad has happened. Indeed there is recent, though admittedly limited, support to show that even kindergarten children can take mitigating circumstances into account when evaluating an aggressor (cf. Karniol, 1978, p. 84), whereas Darley, Klossom, and Zanna (1978) found no age differences between 6-, 9-, and 24-year-olds regarding the use of contextual information in evaluating intentional behavior. In any event, significant distinctions between these two criteria did not emerge in a sequence consistent with a developmental interpretation of Heider's (1958) levels. Moreover, not even adults made a significant distinction between the theoretically easiest level pair (Levels 1 and 2), a result also found by Harris (1977). It would thus seem that the difference between actor-caused accidental events (Level 2) and accidents not produced by actors (Level 1) may not be as important in AR as other Heiderian criteria.

Finally, a scalogram analysis based not on the intensity of responsibility attributed but rather on its absolute ascription showed that Heider's levels formed a Guttman scale. Within the age range tested, only limited and rather ambiguous support was found for age-related response patterns. Under conditions that did not prejudice the youngest group's attributions, no age differences were found in scale scores. However, inspection of the data conforming to scale types did show that undifferentiated responses were exclusive to the child sample and were especially evident in younger children. In addition, adults tended to dominate in the groups that based AR on intentional but justifiable acts and on foreseeable actor-produced accidents. Since these results reflect individual response pat-

terns rather than between-subjects mean scores, they may prove to be a more appropriate test of the developmental support for Heider's theory. In the absence of previous research utilizing such an approach, this result requires replication before the developmental status of Heiderian criteria for attributing responsibility can be fully evaluated.

It should be noted that although Heider's attribution criteria were strongly confirmed, no evidence was obtained in this study to support the additional level hypothesized. Nonetheless, abandoning this criterion is felt to be premature for two reasons. First, it seems to be an extension logically implied by Heider's model. Second, it may not have been appropriately tested in the present circumstances. Because of a medium-intensity negative outcome, a maximal environmental force against the action may already have been broken at the intentionality level leading to the ceiling effect observed. This could be the case for all negative-outcome events, and hence the distinction may only emerge under neutral- or positive-outcome conditions.

To test this hypothesis the same within-subjects Latin square design was used to administer stories representing both positive and negative outcomes at Levels 4, 5, and 6 to 45 adults. Although no substantial evidence was obtained to support Level 6 (differences obtained were, however, in the predicted direction), the interaction between level and outcome was mainly owing to the extreme evaluations of negative outcomes at Levels 5 and 6. In fact subjects estimated that very few persons would have acted as the story character did at these levels (8% and 9%, respectively), supporting the idea of a ceiling effect for internal causation. In contrast, it was held that the behavior of large percentages of people would be similar to that of the story character for positive outcomes (Level 5 = 55%, Level 6 = 42%). These estimates of the action occurring given the situational circumstances suggest that Level 6 was not adequately operationlized to produce maximal internal causality in this condition. It appears that while an extension of Heider's scheme for negative outcomes may be questionable, its utility for positive events remains to be adequately evaluated.

A third aim of the present study was to investigate attribution differences relating to the other and the self as actor. As predicted, this variable interacted with age, but the direction of the difference was contrary to that expected. Inspection of the raw data showed that almost half of the children attributed maximum blame to themselves regardless of level, a phenomenon not found in the other-as-actor condition. In view of this anomaly, the study was repeated on an independent sample of 40 6-year-olds. Since it was suspected that the previous results might reflect a conservative simplifying strategy adopted in the presence of any uncertainty regarding the stimulus story conditions, children were individually tested, while finger puppets were used to further clarify the story presentation. Although the general pattern of increasing AR with level was found, no self/other differences emerged. This result is consistent with Keasey's (1977) finding that children in kindergarten but not in first grade show greater use of intention information in relation to the self than in relation to a hypothetical other. It thus appears that the difference initially found is an artifact that, as mentioned, may merely indicate a simplifying strategy.

A further purpose of the study related to differences between two measures of subjects' attribution, which are often assumed to represent a single entity. Strong evidence to support the hypothesized distinction was found. Whereas all but one group correctly distinguished association and mere causality in terms of perceived causality, no group made this distinction in attributing blame. In addition, responses to perceived blame formed a Guttman scalogram, whereas perceived causality did not. These two findings represent an interesting qualification to Heider's (1958) theory, because both measures have been cited as indications of responsibility (e.g., Harris, 1977).

The utility of these two attribution measures for developmental research was also

illustrated. While adult distinctions regarding blame were achieved by 10 years of age, no child group showed the adult response pattern for causality attribution. Children tended to perceive differences in causality where adults did not, suggesting that causality and responsibility were not as clearly distinguished. Furthermore, increasing age was associated with the emergence of a clear pattern in the use of the two attribution measures. Whereas younger children sometimes ascribed greater blame than causality, adults rarely did so (6 years = 28% of total responses, 8 years = 24%, 10 years = 20%, 12 years = 17%, and adults = 10%). Any response order effect due to regression would not alter the above result, which is consistent with the age-related changes in the data curves for both dependent measures and suggests a similar increasing cognitive differentiation between perceived blame and causality with age.

The results of this study also support an emerging belief that even young children differentiate intentional from unintentional behavior and are capable of more subtle distinctions in their attributions than are traditionally ascribed to them. That children as young as 6 years clearly distinguished accidental and intentional outcomes is consistent with recent research (e.g., Farnill, 1974) showing that children do use intentionality information when tested under appropriate conditions that do not overburden their cognitive processing capacities.

In sum, the present study provides some support for a developmental interpretation of Heider's (1958) levels of AR. When quantitative group scores were considered, all ages made theoretically consistent distinctions between the levels, although a greater number of significant differences was associated with increasing age. Similarly, certain response patterns dominated at particular ages, but no evidence was found for developmental stages. Insofar as developmental differences do exist, a potentially fruitful question for future research to answer is whether they represent age-related variations in evaluative criteria or social perception.

Multiple Discovery and Invention: Zeitgeist, Genius, or Chance?

Dean Keith Simonton
University of California, Davis

The occurrence of independent contributions by two or more scientists can be interpreted in terms of zeitgeist, genius, or chance. The relative adequacy of these three theories was examined by hypothesizing four critical empirical tests. These tests focus on (a) the general and intradisciplinary probability distribution of multiples and (b) the relationship of individual eminence with multiple production and priority. An analysis of 579 multiples and of 789 scientists and inventors lends the most support to the chance theory, followed by the zeitgeist theory. The results are integrated into a single probabilistic perspective that incorporates some of the major features of all three theories.

What mathematician does not know that the calculus was independently devised by both Newton and Leibniz? Who among biologists has not heard that Darwin's laborious documentation of evolutionary theory was almost forestalled by an independent abstract by Wallace? And what psychologist has not observed to his or her students that the James–Lange theory of emotion was actually advanced independently by James and Lange? Certainly the occurrence of multiple discoveries constitutes one of the most fascinating phenomena in the history of science and technology. Such multiples become particularly dramatic when they provoke fierce priority disputes such as the debates that surrounded the independent prediction of the planet Neptune by Adams and Leverrier. But why do multiple discoveries and inventions happen at all?

The traditional explanation of multiples is founded on what can be called the *zeitgeist* theory of creativity. According to this social deterministic view, the individual creator is largely irrelevant or epiphenomenal to the cultural progress represented by the inevitable accumulation of scientific knowledge and technological expertise. Rather, it is the sociocultural system as a whole, embodied as the spirit of the times, which is ultimately responsible for any given technoscientific advance. Thus, if neither Adams nor Leverrier had predicted the existence of Neptune, someone else would certainly have done so. The failure of gravitational astronomy to explain the anomalies in the orbit of Uranus became so obvious and irksome that Neptune's forecast was in the air. Because the times were ripe for the prediction of the eighth planet, it was really immaterial who actually picked the fruit; any competent astronomer might have done the same, had Adams and Leverrier both died in the crib. Not surprisingly, the zeitgeist account of multiples is frequently defended by those anthropologists and sociologists who desire to minimize the role of the individual as a causal agent of sociocultural events. For example, in an article entitled "Are Inventions Inevitable?" Ogburn and Thomas (1922) list nearly 150 multiples to prove that any given discovery or invention has a probability near unity of appearing, the presence or absence of any specific genius notwithstanding. And Merton (1961) takes this interpretation so much as given that he once asserted, "It is the singletons—discoveries made only once in the history of science—that are the residual cases, requiring special explanation" (p. 477). But psycholo-

gists are not always ill-disposed to the zeitgeist interpretation of multiples, as we can readily witness in Boring's (1963) citation of multiples as evidence that the "genius" is merely an agent of the zeitgeist, an effect or a symptom rather than the cause of the times.

Still, there is no doubt that not all psychologists would completely endorse the zeitgeist position. The assumption implicit in the research on creativity in the 1950s and 1960s was that substantial and sustained individual differences in creativity determine whether any given person can make a contribution to society (e.g., Taylor & Barron, 1963). In short, many psychologists would feel much more comfortable with what can be styled the *genius* theory of creativity. According to this perspective, scientific discoveries and technological inventions are produced by great scientists and inventors who possess abilities, personalities, and backgrounds that set them apart from their colleagues. On first blush, it would seem that the genius theory could not adequately explain the appearance of independent contributions, but this supposed inadequacy is only partly true. In fact, genius theory can explain one aspect of multiples that must prove an embarrassment to zeitgeist theory—the frequent occurrence of rediscoveries. Not all multiples are produced simultaneously. The various independent contributions are sometimes separated by long time spans during which the first invention or discovery passes into temporary oblivion. Merton (1961) has reported that even though 20% of the multiples he studied occurred within a 1-year span, some 34% entailed a time lapse of 10 or more years. Classic instances of rediscoveries include Mendel's formulation of the laws of heredity, some of Cavendish's unpublished electrical discoveries, much of Gauss's unpublished mathematical work, and the prodigious notebooks of one of the greatest anticipators of all, Leonardo da Vinci. How can someone like Mendel come to be 35 years ahead of his time? Genius theory has less difficulty on this point: A major genius is defined as one who transcends the limitations of the zeitgeist and one who may even anticipate movements far into the future. Long delayed rediscoveries can be adopted, therefore, as evidence for genius theory. For example, even if Stevinus merely rediscovered hydrostatic principles already known to Archimedes, the fact would remain that it took almost 2,000 years for someone to be born who could replicate Archimedes' achievement.

Besides the genius and zeitgeist theories, a third position is a credible contender for understanding multiples: *chance* theory. Since most behavioral scientists seem to go out of their way to disprove the null hypothesis predicated on the random model (Greenwald, 1975), it is perhaps unsurprising that this theory has not always received the study it deserves. Nonetheless, chance or "luck" definitely plays some part in creativity, as the phenomenon of serendipity well illustrates (Cannon, 1940). In addition, probabilistic or stochastic models have been so successfully applied to other facets of creativity that there is no reason not to approach multiples in the same manner. To illustrate, probability models have explained individual differences in creative productivity (Price, 1976; Simon, 1955), the correlation between productivity and eminence (Dennis, 1954), and the correlation between productivity and age (Dennis, 1966; Simonton, 1977a). More specifically, there have been several investigators who have proposed some kind of probability model for multiples (e.g., Price, 1963, chap. 3; Schmookler, 1966, chap. 10; Simonton, 1978). As an example, many adherents of the zeitgeist perspective believe that the near simultaneity of many inventions or discoveries precludes explanations based on mere chance (e.g., Kroeber, 1917). Such multiples as the liquification of oxygen by Pictet and Cailletet, the discovery of the stereochemistry of carbon by Van't Hoff and Le Bel, the electrolytic process for aluminum manufacture of Hall and Heroult, and even the rediscovery of Mendelian genetics by De Vries, Correns, and Tschermak all took place not simply within a year but often within a month or so. For chance theory to handle this simultaneity, we have only to assume that once a given contribution is made, the probability of a duplication declines rapidly due to communication termi-

nating any research that might head in the same direction.

Each of the foregoing three theories can be offered as partial interpretations of multiples in science and technology. But which theory best explains the data? In this article I propose to examine each of the three principal theories so as to derive a set of distinctive empirical predictions that can serve as critical tests. In deriving these distinguishing repercussions of the three theories, I will treat each position as a pure or ideal type. In other words, I will try to make each theory as distinctive as possible so that the contrasting empirical implications can best be highlighted. Only at the close of this article, after the results of the tests are known, will I attempt to synthesize the three theories into a single view. With this qualification in mind, we can advance the following four tests.

Test 1

If the zeitgeist theory holds, then multiples should be very common relative to singletons, and the distribution of the various grades of multiples (i.e., doublets, triplets, quadruplets, quintuplets, etc.) should be approximated by a binomial distribution with a mean appreciably greater than 1. If the genius theory holds, then multiples should be virtually nonexistent, yielding a degenerate binomial with a mean of 1 and a variance of 0. If the chance theory holds, then multiples should be rare relative to singletons, and the distribution of the various grades of multiples should be approximated by a Poisson distribution with a mean less than 1.

Let us suppose that for any given invention or discovery there are n individuals capable of producing it, and each has a probability p of success, where $n \geq 1$ and $0 < p \leq 1$. Then, as we know from any introductory statistics text (e.g., Snedecor & Cochran, 1967, chap. 8), we can employ the binomial distribution to obtain the proportion of the various numbers of successes. Now suppose we apply this simple probability model to the three theories. If the zeitgeist theory is valid, then the number of

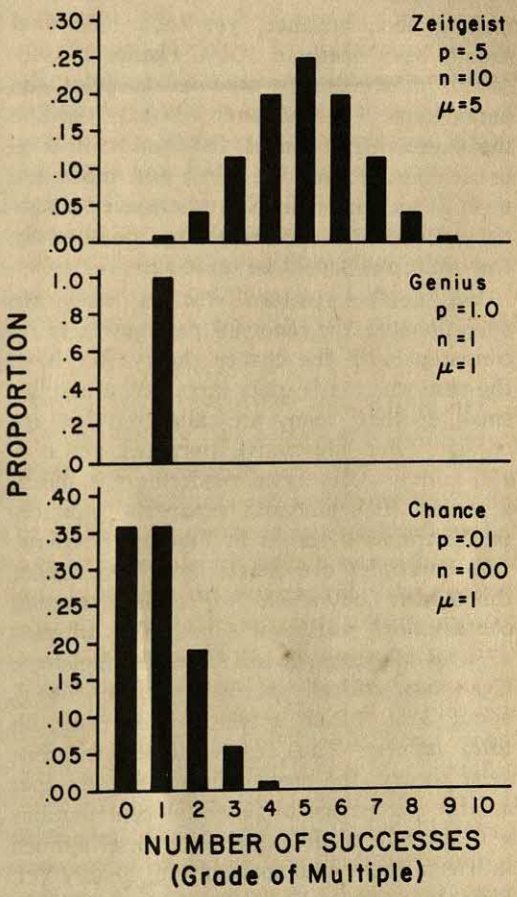

Figure 1. Predicted probability distributions obtained by interpreting the three alternative theories in terms of the binomial distribution with different values for n and p.

creators should be very large and the probability of success somewhat small, so that genius per se is irrelevant. Assume for the sake of argument that $p = .5$ and $n = 10$, that is, that for any potential contribution there are 10 people capable of making it, although each enjoys only a 50–50 chance of success. Then we should obtain a binomial distribution with a mean of $np = 5$ and with the shape shown in Figure 1. Under this distribution almost 99% of all contributions to science and technology will involve two or more independent creators, and the modal multiple will be of Grade 5 (i.e., quintuplets). Hence, inventions and discoveries must be virtually inevitable.

If the genius theory is correct, there should be only a small number of people capable of

making each advance, yet each individual should have nearly a 100% chance of success. For argument's sake let us posit the parameters of $n = 1$ and $p = 1.0$, yielding the degenerate binomial distribution in Figure 1. Notice that the mean and mode are now 1, with no multiples whatsoever occurring. Hence the genius theory does imply that multiples should be quite rare.

Yet another picture emerges when we operationalize the binomial parameters to be consistent with the chance theory. We have the case where n is quite large but p is quite small, so that "many are called but few are chosen." For illustrative purposes, let $n = 100$ and $p = .01$, again rendering the mean, μ, unity. The binomial expansion produces the distribution shown in Figure 1. Observe that multiples are much more rare under this model: Only about 26% of all attempted contributions will involve multiples, whereas 37% of all attempts will produce singletons. Even more critically, according to this model, about 37% of all attempts will result in total failures. Thus, quite unlike the zeitgeist theory, the chance theory implies that a large percentage of potential contributions will never be made and thereby inserts much indeterminancy into sociocultural history (cf. Simonton, 1978). Furthermore, if the chance theory is true, then we may go one step further and assert that the frequency distribution of multiples of various grades will be closely approximated by a Poisson distribution. The latter is the exponential limit of the binomial distribution when n is very large and p is very small (Haight, 1967, p. 15). For example, the correlation between proportions derived from a Poisson distribution with $\mu = 1$ and those from a binomial distribution with $n = 100$ and $p = .01$ departs from unity only after the fourth decimal place. Also, since the mean and variance are equal in the Poisson case, the Poisson distribution is easier to estimate from limited data, a valuable asset, given that we do not know how many total failures there have been in the history of science and technology (i.e., how many "nulltons"). For this first test the Poisson distribution will therefore be adopted as the hypothesis to be disproven. Only if we are empirically compelled to abandon the Poisson model with a mean less than 1 will we feel obliged to examine the two alternative theories.[1]

Test 2

According to the zeitgeist theory, the probability of multiples occurring should be highest in the mathematical and physical sciences and lowest in the biological sciences. If the genius theory is correct, the reverse should be true. But by the chance theory, the probability that multiples will occur should be constant across scientific disciplines.

Some scientific endeavors can be said to engage more zeitgeist than others. As Kuhn (1970) pointed out, the physical sciences often have well-developed paradigms that logically generate the puzzle-solving research of "normal science." Thus the problems of classical physics were largely defined in terms of the repercussions of Newtonian mechanics and Maxwellian electromagnetic theory. Other, "softer" sciences do not feature such clean theoretical foundations, and consequently the zeitgeist is more diffuse. Hence we would expect the more codified and mathematically constructed disciplines to generate a disproportionate number of multiples. The prediction of genius theory goes almost in the opposite direction. Genius theory maintains that the major figures of human history tend to transcend the spirit of their times. Indeed, a study of more than 2,000 thinkers in Western civilization has

[1] Actually, we could argue that a more reasonable probability distribution would be the negative binomial (Simonton, 1978). This "contagious" or "compound" Poisson allows the parameter $\mu = np$ to be described by the gamma distribution, and accordingly the probability that a contribution will appear does not have to be a constant (Fisz, 1963, pp. 164–168). Yet if the chance theory holds, we must recognize that the Poisson distribution is also the exponential limit of the negative binomial, and consequently we do not gain additional predictive power (Feller, 1968, p. 281). In fact, there would be a loss due to the inability to apply the usual estimation techniques for the truncated negative binomial to the current data set (e.g., Brass, 1958).

shown that there is a negative relationship between the fame of a thinker and the extent to which he or she fits the prevailing beliefs of the time (Simonton, 1976d). Accordingly, those disciplines that attract the most geniuses should have a smaller proportion of multiples. But how do we know which scientific enterprises attract the greatest minds? Roe (1952) found in her study of 64 eminent scientists that physicists tend to score higher on standard intelligence tests than do biologists. Similarly, Harmon's (1961) survey of doctorates discovered that physicists and mathematicians had higher intelligence quotients than biologists, with chemists and engineers falling in between. Therefore, if we are willing to grant two crucial assumptions, we would predict in accordance with Test 2. The first assumption is that the distribution of intelligence in contemporary science can be projected a few centuries into the past. Partial support for this extrapolation can be gleaned from Cox's (1926) IQ estimates for select scientists born as far back as the fifteenth century: Mathematicians have an average IQ of 183, physicists 178, medical researchers 172, chemists 172, biologists 171, and astronomers 170. The second assumption is that psychometric IQ has something to do with cultural eminence. While classic studies of contemporary populations by Terman and Oden (1947) and of historical populations by Cox (1926) have attempted to demonstrate this relationship, the evidence is far from secure. For instance, the correlation of .26 that Cox found between eminence and IQ has been shown to be a methodological artifact (Simonton, 1976a). Nevertheless, without this assumption we cannot derive a unique prediction for the genius theory. Finally, turning to the chance theory, we see that the random model is the simplest, for it merely affirms that the probability of the coincidences labeled as multiples is uniform across all disciplines. A recent reanalysis of data published by Ogburn and Thomas (1922) seems to endorse this latter prediction (Simonton, 1978). Nonetheless, the sample size may have been too small to permit rejection of the null hypothesis.

Test 3

The zeitgeist theory implies that there should be a positive relationship between the eminence of a given scientist or inventor and the number of multiple discoveries or inventions he or she participates in. In contrast, the genius theory implies that the relationship between eminence and multiples participation should be negative. The chance theory predicts that this correlation should be zero once variations in productivity are controlled.

Boring (1963) believed that certain historical figures are singled out as "eponyms" because they epitomize the times in which they live. If multiples are also interpreted as zeitgeist-inspired events, then it follows that the eponyms of history should engage in more multiples than those outcasts from the mainstream of history. Thus Merton (1961) has maintained that persons of "great scientific genius will have been repeatedly involved in multiples" (p. 484). The genius theory would advocate the exact opposite. To employ Kuhn's (1970) terminology again, the lesser figures may be wrapped up in the puzzle-solving activities dictated by the predominant paradigms of normal science, but the principal figures are generating influential scientific revolutions that will change the zeitgeist. On the other hand, chance theory takes a stance somewhere between these extremes. As Merton (1961) noted, the more eminent scientists produce more multiples in part "because the genius will have made many scientific discoveries altogether" (p. 484). So just by chance the more productive scientist will create more multiples. Yet creative productivity has been repeatedly shown to be correlated with eminence (e.g., Dennis, 1954; Simonton, 1976b). Hence, there may very well be a positive correlation between eminence and participation in multiples, but that correlation may be the spurious result of a common cause, creative productivity. Therefore, if we partial out the source of spuriousness, the relationship should vanish, at least according to chance theory.

Test 4

If the genius theory is justified, there should be a positive relationship between individual eminence and temporal priority in a multiple. If either the zeitgeist or the chance theory holds, there should be no relationship, positive or negative.

As already noted, the genius not only is independent of the zeitgeist but may also be a precursor of the future zeitgeist. Hence, the more eminent scientist produces inventions or discoveries far in advance of his or her time, contributions that lesser minds may take decades if not centuries to rediscover. Unfortunately for this prediction, past research is not in complete accord with the precursive conception of genius. The study of more than 2,000 thinkers mentioned earlier found that the more eminent thinkers were actually behind their times, as if they were more interested in consolidating the past than in intimating the future (Simonton, 1976d). If this result applies to science and technology too, then the major figures may be those who rediscover the work of lesser known predecessors. In any case, we would not expect any consistent relation between priority and eminence, should the zeitgeist or chance theories prove valid.

Quite clearly the above four tests do not all have the same secure foundation. The conceptual basis for Tests 1 and 3 is perhaps more firm than for Tests 2 and 4. Even so, something is definitely gained by stipulating both strong and weak criteria for the three theories. Although the three approaches do not always imply three separate predictions for each test, each of the theories is uniquely characterized when all four tests are taken together. If both weak and strong tests point in the same direction, then the preferred theoretical explanation can be better identified. In addition, the outcome of all four tests may provide the basis for a synthesis of the three theories into a single, more comprehensive view.

Empirical Tests

How Probable Are Multiples?

Clearly our first task is to obtain an extensive list of multiples. To do this I began with the previously published lists of Ogburn and Thomas (1922), Kroeber (1963), and Stern (1927, chap. 3).[2] This preliminary list was then augmented by consulting a large number of additional sources, especially Darmstaedter (1908), Taton (1964, 1965, 1966), Asimov (1972), and Williams (1974). I also attempted to verify all purported multiples to make sure they actually involved independent efforts of two or more researchers (using, e.g., Debus, 1968; *Encyclopædia Britannica*, 1974; Gillispie, 1970; Singer, Holmyard, Hall, & Williams, 1958). A critical theoretical issue arose at this verification stage: The case for the occurrence of multiples is not as strong as one is led to believe by zeitgeist enthusiasts. One problem is that many putative instances rest on vague generic terms that may encompass far too much (Schmookler, 1966, chap. 10). For instance, Ogburn and Thomas (1922) credit both Boerhaave and Hales with the independent contribution of the "beginnings of modern organic chemistry" (p. 98), an extremely general attribution, to be sure. Another difficulty is that even more specific terms, such as the "microphone," may cover inventions or discoveries that are often comparable only regarding function, each contribution employing quite different means to attain roughly the same end. Indeed, it may even be argued that true multiples are virtually nonexistent: The calculus of Newton was not the same as that of Leibniz, nor was Priestley's oxygen generated the same way as Scheele's. Even the eighth planet differed from Adams to Leverrier, since each predicted different orbits for Neptune (both of which just happened to coincide fairly well in 1846). Yet even granting some abstraction in categorization, many multiples still prove to be mirages upon closer inspection. Often what is described as independent work is not independent at all. Thus Ogburn and Thomas (1922) should not list both Henry and Morse as inventors of the telegraph, for it was Henry's freely given advice that had allowed a painter to succeed. Similarly, Morton learned of the anesthetic properties of ether

[2] I attempted to obtain Merton's (1961) sample as well, but his data are no longer available (Merton, Note 1).

from Jackson, and Fulton well knew Jouffroy's work on the steamboat and actually attended the launch of Symington's steamboat (cf. Ogburn & Thomas, 1922). In short, many multiples do not involve independent efforts but rather consecutive developments in the evolution of science and technology (cf. Constant, 1978). A final problem is that a multiple mentioned in one source might not be mentioned in any other source and hence would stand unconfirmed.

To deal with the foregoing problems, I chose to collect two separate samples of multiples (excluding cases prior to 1500) from the general fields of mathematics, astronomy, physics, chemistry, biology, medicine, and technology. The first, "exclusive" sample included only those multiples mentioned in two separate sources, without contradiction by any other source. The second, "inclusive" sample consisted of all multiples mentioned in at least one source as long as no contradictory evidence could be found in any other source. The exclusive sample contained 199 multiples, more than the 148 collected by Ogburn and Thomas (1922) but less than the 264 gathered by Merton (1961). The more liberal definition added another 380 multiples to produce the 579 multiples of the inclusive sample. All principal hypotheses were then tested on *both* samples. Fortunately, the substantive conclusions do not materially differ for the two samples, and I will therefore focus on the inclusive sample (since a larger sample size permits parameter estimates with smaller standard errors).

General probability (Test 1). One secure finding is that multiples are extremely rare events. It may sound impressive to assert the existence of 579 potential multiples, but the number of so-called singletons is immensely larger. To illustrate this point, we may note that Darmstaedter's (1908) chronology, probably the most comprehensive in any Western language, lists 12,300 contributions in the seven fields represented in our sample (Sorokin, 1957, Table 5). So at best multiples constitute a mere 5% of all contributions. I say "at best" because the Darmstaedter chronology is evidently more selective than the undefined sample from which the multiples were apparently derived; most of the purported multiples were not sufficiently important to be cited in that source. Consequently, the zeitgeist theory seems disproven: As we can conclude from Figure 1, singletons are supposed to be far less common than multiples if the zeitgeist theory holds. In fact, the results thus far appear to partly bolster the genius theory.

An advocate of the zeitgeist position, however, may claim that it is most unfair to compare singletons to multiples. Merton (1961) presented 10 reasons why he believes that multiples are considerably underestimated and that many singletons may actually be multiples incognito. On first glance, this accusation, if true, would seem to invalidate any empirical investigation and would thereby transport the whole issue to the realm of armchair social philosophy. But inquiry can be salvaged if we ignore the singletons altogether and instead concentrate on the probability distribution of multiples of various grades (Simonton, 1978). We have only to assume that the relative proportions of doublets, triplets, quadruplets, and so on remain constant after being sifted through the selection process. If there are twice as many doublets as triplets in the real world (i.e., the statistical population), there will presumably be twice as many doublets as triplets in any sample, once we allow for sampling error. Given this standard assumption of statistical sampling, we can then try to fit a truncated Poisson distribution using the two-moments method of estimating the mean, μ, and the standard error, *SE* (Haight, 1967, p. 89; Patil, 1962). The result is displayed in Table 1, where I give the observed frequency of multiples of Grades 2 through 8 along with the fitted values according to a Poisson model (using the tables in Molina, 1942).

The fit is fairly close. A goodness-of-fit test gives $\chi^2(3) = 6.07$, $p > .1$ that any discrepancies are due to mere chance. Although this test does not strictly prove the chance theory, we can be very confident that both the zeitgeist and the genius theories are disconfirmed. This conclusion is reinforced when we inspect the estimated mean, which is less than 1. This mean implies that contributions are made less than once, on the average. Accordingly, a large proportion of potential

Table 1
Observed Frequencies of 579 Multiples and Frequencies Predicted by a Poisson Model With $\mu = .82$

Multiple grade	Observed frequency	Predicted frequency
0	—	1361
1	—	1088
2	449	435
3	104	116
4	18	23
5	7	4
6	0	0
7	0	0
8	1	0

Note. Poisson parameters were estimated using the two-moments method. The standard error of the estimate is .12.

contributions never appeared at all. Given a mean of about .8 we would expect, by the Poisson Model, that some 45% of all potential contributions would become nondiscoveries or noninventions, about 36% becoming singletons, and the remaining 19% multiples. Given this outcome, scientific or technological advance is not very inevitable, to say the least.

I hasten to point out that it would be very difficult for zeitgeist theory to save the day by simply finding more multiples. It is my experience after two years of collecting multiples that the more multiples one teases out of history, the worse the picture becomes for any social deterministic outlook. What is required is more high-grade multiples—more triplets on up—in order to give the distribution a larger mean, less right skewness, and an approximately inverted U shape instead of the monotonically decreasing form. But that is not what happens. The quest for more multiples tends to dig up more doublets, rendering the case for the chance model stronger rather than weaker. Thus if we examine just the exclusive sample of 199 multiples, we find that there are 144 doublets, 42 triplets, 9 quadruplets, 3 quintuplets, and 1 octuplet. The two-moments estimate of the mean is 1.06 with a standard error of 1.33, $\chi^2(3) = 3.37$, $p > .25$. Even though this mean falls within the interval estimate for the inclusive sample, it still is larger. Hence the addition of more multiples actually lowered the mean, making the distribution more skewed right by the disproportionate addition of doublets.

I should also observe that the Poisson distribution proves to be an acceptable fit only if the singletons are excluded. Otherwise, I know of no probability model that will fit the data. We therefore have two choices. On the one hand, we can accept the observed relative frequencies of singletons and multiples as being realistic, in which case the genius theory is favored. On the other hand, we can ignore the singletons and look only at the probability distribution of multiples, in which case the chance theory is favored. The zeitgeist theory could not explain these results without adding some post hoc interpretation.

Probabilities within disciplines (Test 2). If we subdivide the multiples into the seven fields, we discover that there are 53 multiples in mathematics, 28 in astronomy, 115 in physics, 78 in chemistry, 33 in biology, 184 in medicine, and 88 in technology. By comparison, Darmstaedter (1908) lists 329 contributions in mathematics, 478 in astronomy, 1,511 in physics, 2,469 in chemistry, 1,415 in biology, 1,268 in medicine, and 4,830 in technology (Sorokin, 1957, Table 5). Hence, as an approximation we may assert that 16% of mathematics, 8% of astronomy, 8% of physics, 3% of chemistry, 2% of biology, 14% of medicine, and 2% of technology involves multiples. Except for the high proportion in medicine, these percentages seem to support the zeitgeist position in Test 2: The more codified and mathematical disciplines do appear to have a larger proportion of multiples. But again, this conjecture hinges on the assumption that the comparison of multiples and singletons is justified. Do we obtain collaboration when the probability distributions are studied?

Table 2 shows the observed frequency distributions as well as the Poisson statistics and goodness-of-fit tests for each of the seven fields. Observe that the Poisson model again provided an adequate fit, even though in no case can we assert that the chance theory is strictly proven. The means also vary from one field to another, but not in a manner consis-

Table 2
Multiple Frequencies and Poisson Statistics Within Disciplines

Item	Seven fields

tent with either the zeitgeist or the genius theories. In fact, the standard errors of the estimates are so large that we cannot reject the hypothesis that all the sample means come from the same population mean.[3] Further reason for doubting the substantive significance of any mean differences comes from the fact that the magnitudes and ordering of the means in Table 2 are not very consistent with those found in a secondary analysis of the Ogburn and Thomas (1922) data (Simonton, 1978). Hence, this part of Test 2 seems to endorse the chance theory. If we reject the proportion of multiples to singletons as meaningless, then the probability that a multiple will appear is roughly the same across all disciplines.

Who Participates in Multiples?

Eminence, multiples, and creative productivity (Test 3). To scrutinize Test 3 empirically, we must first obtain a sample of creators. This end was accomplished by taking all those scientists and inventors with entries in either Asimov (1972) or Williams (1974) who were born on or after 1500 and who died on or before 1909. (The latter date was selected to maximize the number and quality of sources available for operationalizing creative productivity.) The result was a sample of 789 scientists and inventors. The eminence of each was determined by using the *Encyclopædia Britannica* (1974), a source shown by previous studies to yield reliable estimates of individual eminence (e.g., Simonton, 1976a, 1976d, 1977b). A scientist or inventor was given 3 points if included in the selective *Macropædia,* 2 points if given a "major entry" in the more inclusive *Micropædia,* 1 point if only given the terse "subsidiary entry" in the *Micropædia,* and 0 points if not included at all. Creative productivity was measured by counting the number of contributions listed in Darmstaedter (1908), a source shown to be very reliable for the period covered (Simonton, 1975, 1976b, 1976c). Finally, for each scientist or inventor I tabulated the number of multiples in which he or she participated. When we calculate the zero-order Pearson product–moment correlation coefficient between eminence and the number of multiples produced by an individual we find the statistically significant value of .25 ($p < .001$). So far, the zeitgeist theory is supported. Nonetheless, creative productivity correlates .32 ($p < .001$) with eminence and .42 ($p <$

[3] Even though we did not prove the Poisson model to be the best possible fit, the data are definitely far from being normally distributed. Therefore, it seems far more reasonable to base statistical tests on the standard error of estimate for each Poisson μ.

.001) with the number of multiples. Because the more eminent creators are more productive regarding both singletons and multiples, the correlation between eminence and multiples may be spurious, as chance theory predicts. Calculation of the first-order partial correlation between eminence of multiple productivity controlling for creative productivity yields a value of .14 ($p < .001$). We are now in something of an interpretative quandary. On the one hand, this partial correlation remains highly significant statistically, and consequently the zeitgeist theory seems justified. The more eminent creators are more likely to participate in multiples even after controlling for individual differences in the number of notable contributions. On the other hand, the substantive significance of the partial correlation is small, given that only 2% of the variance in eminence and multiple participation is shared after controlling for creative productivity. So in a substantive sense, the effect of zeitgeist is so small that we might adopt the chance theory as the main explanation.

Since we are forced to interpret such small effects, I decided to attempt a replication using different operationalizations of eminence and creative productivity. This time eminence was defined using the earlier edition of Asimov (1964), which makes finer distinctions regarding relative fame. A creator was given 3 points if he or she had a "major entry" in Asimov, 2 points for a "subsidiary entry," 1 point for only a listing in the index, and 0 points for no listing at all. This measure of eminence correlated .45 with the one previously derived from the *Encyclopædia Britannica* (1974). This interitem reliability coefficient compares quite favorably with intertest reliabilities for creativity and intelligence measures on selective populations (see, e.g., Wallach & Kogan, 1965). The alternative measure of creative productivity was not taken from a single source, but rather consisted of all contributions listed in a large number of separate chronologies (viz. Auerbach, 1923; Boyer, 1968; Dannemann, 1928; Daumas, 1957; Feldhaus, 1904; Gabriel & Fogel, 1955; Garrison, 1929; Grun, 1975; Hilditch, 1911; Langer, 1972; Mayer, 1949; Mumford, 1934). This second measure correlated .79 with that derived solely from Darmstaedter (1908). When we calculate the correlation between the two new measures of eminence and multiples we obtain .26 ($p < .001$), a value hardly differing from that obtained earlier. Moreover, the new measure of creative productivity correlates .37 ($p < .001$) with the new fame measure and .48 ($p < .001$) with the number of multiples, values only modestly larger than those calculated formerly. Therefore, it should come as no surprise that the partial correlation between eminence and multiple participation controlling for creative productivity is reduced only slightly to a still statistically significant .10 ($p < .05$). So the results we have obtained are extremely robust. In fact, no matter which combination of fame and creative productivity measures we employ, the outcome is essentially unaltered. Further, the same basic results emerge even if we employ only the exclusive sample of multiples.

It is manifest that the genius theory cannot explain the results. In addition, since the correlation between eminence and multiple production remains even after controlling for creative productivity, the zeitgeist theory has some credence. Nevertheless, partialing out creative productivity reduces the correlation to such a small value that the chance theory is not altogether ruled out as long as a modest zeitgeist influence is permitted.

Eminence and priority (Test 4). Are the more famous creators more likely to get there first, leaving their lesser colleagues the frustration of rediscovering the already known? To answer this question we first must be able to distinguish the relative eminence of each participant in a multiple. We have already shown how Asimov (1964) and the *Encyclopædia Britannica* (1974) could be used for this purpose, and the scores from these sources can be summed to produce an eminence measure ranging from 0 to 6. However, since many multiples involve obscure individuals, this composite score would not discriminate very well among the virtual nonentities. Therefore, possession of an entry in the extremely comprehensive reference edited by Debus (1968) added another point to the

composite score, generating an index ranging from 0 to 7.

Since the possible rank orderings vary depending on the grade of the multiple, it makes more sense to apply this eminence measure to each grade separately. An examination of doubles reveals that of the 449 cases, the data were insufficient in 63 to estimate the relationship between eminence and priority (usually because the two contributors were equally obscure). Of the remaining cases, the contributions were simultaneous in 197, the more eminent creator had priority in 79, and the less eminent creator had priority in 110. The preponderance of simultaneous contributions may be taken as evidence against the genius theory. I strongly suspect, however, that this proportion would be reduced if dissertation-sized research could be devoted to each case (e.g., the proportion of simultaneous multiples is much smaller for the exclusive sample that involves better documented cases). Much more curious is the fact that the priority assignments, when not simultaneous, are definitely contrary to the genius theory, at least as presumed in Test 4. The more eminent creators are more likely to be the rediscoverers, whereas the less eminent creator is more likely to have priority, $\chi^2(1) = 5.08$, $p < .01$. Perhaps the eminent scientist, like the eminent philosopher, is behind the times (cf. Simonton, 1976d). In the process of consolidating past advances, the major scientist may inadvertantly rediscover much of the work of various predecessors. Therefore, this outcome might be taken as support for the genius theory if we change our perspective on the genius from precursor to consolidator. Nonetheless, even if we grant this post hoc amendment, the impact of genius must be small, given the prevalence of simultaneous contributions.

Because the higher grade multiples are so few in number, inferences are necessarily less secure. Among triplets, the contributions are simultaneous in 36, the most eminent creator first in 15, second in 13, and third in 17 (the remaining 23 being unclassified for reasons given above). For quadruplets, 4 are simultaneous, and the most eminent creator is first 5 times, second twice, third twice, and last once (with 4 cases unclassified). Among quintuplets, there are no simultaneous multiples, the most eminent creator is first in 3 instances, and the third, fourth, and fifth places have 1 case each (and one unclassified). Finally, the single octuplet can only be considered a simultaneous multiple due to the plus or minus on the dating. Hence the whole picture suggests some tendency for the more eminent creators to have priority for the higher grade multiples, but none of these comparisons involve enough cases to permit statistical confidence in any conclusions.

Conclusion

The position that best meets all critical tests is the chance theory. Only the chance theory predicts the characteristic probability distribution of multiples and the absence of any probability differences from discipline to discipline. Although chance theory had to yield some ground to zeitgeist theory in Test 3, control for creative productivity considerably reduced the common variance between eminence and multiple participation. So on the whole, chance theory may be the best general explanation of the phenomenon. Despite the apparent explanatory superiority of the chance theory, however, the other two theories are not completely overturned. I think it is significant that the more eminent scientist is more likely to rediscover independently the work of his or her less eminent colleagues. Like the great philosopher, the eminent scientist appears to be a consolidator, synthesizing past achievements (cf. Simonton, 1976d). This consolidative process may sometimes entail some sociocultural redundancy in the form of rediscovery or reinvention. Nonetheless, the fact remains that there exist individual differences in priority, differences that cannot be explained by either chance or zeitgeist theories.

When we turn to zeitgeist theory, we cannot ignore its explanatory value either. We must obviously acknowledge that the zeitgeist is probably a necessary even if not a sufficient determinant of discovery or invention. There can be no denying that some contributions are prerequisites to other contribu-

tions. Certainly the discovery of bacteria presupposes a microscope, and the discovery of Jupiter's moons presumes the existence of a telescope. Nevertheless, the invention of these instruments does not automatically cause the corresponding discoveries for which they are prerequisite. The discoveries may or may not occur after the preconditions have been fulfilled: Galileo's discovery of Jupiter's satellites took place only 1 year after the telescope was invented, whereas Leeuwenhoek's discovery of bacteria happened about 200 years after the simple microscope appeared. So there remains some degree of indeterminancy in the influence of the zeitgeist, an indeterminancy consistent with the chance model.

Allow me to expand the last point: Not only can the zeitgeist and chance theories be seen to provide complementary accounts of multiples, but in addition, all three theories can be made compatible to some extent. Admittedly, I have sometimes oversimplified one or another theoretical outlook in the interest of drawing distinctive empirical predictions. Although advocates of the pure forms for each theory definitely exist (e.g., Kroeber, 1917), many researchers opt for some more moderate combination (e.g., Merton, 1961). By adjusting all three theories in the light of the current data, a more unified perspective on multiples can emerge. This possibility can be readily seen by more closely examining what I consider to be the two principal empirical results of this study.

The first main finding concerns the intercorrelation among individual eminence, creative productivity, and participation in multiples. It is definitely consistent with genius theory to notice a high correlation between the fame of an individual scientist or inventor and the number of contributions he or she makes (Albert, 1975). It is also in line with zeitgeist theory to observe that the more eminent contributor is more likely to produce more multiples. Yet in accord with the chance theory, a large part of the multiple production of more eminent creators is a probabilistic consequence of their greater creative productivity. Hence, all three theories tend to converge to explain the same phenomenon, at least so long as each undergoes some accommodations. The genius theory must permit the eminent scientist to be a major proponent of the current trends in his or her field—and not a dissenter or rebel. Similarly, the zeitgeist and chance theories must each yield some ground in explicating the relation between eminence and participation in multiples. Eminent scientists engage in more multiple production both because they are more productive and because they are more representative of the spirit of their times.

The potential compatibility of the three theories becomes even more evident when we scrutinize the second principal finding, namely, that the frequency of various multiple grades can be described by a Poisson distribution. To simplify the argument, let us suppose the mean of the distribution is somewhat close to unity. Then it may be argued that for any given potential contribution about 25 people are capable of the achievement, each having 1 chance out of 25 succeeding (i.e., $np = 25 \times 1/25 = 1$). These parameters can be made consistent with the genius model if we define the genius as a rare individual who has a probability greater than 0 of making notable contributions. It would be no slight achievement to be one out of a mere 25 persons in all history who are able to create the calculus or evolutionary theory or any other contribution. And even though chance plays a larger role than a pure genius theory might suggest, this interpretation still states that only a select few have any opportunity whatsoever. So serendipity may be ever present, but it is an elitist serendipity when so few have the capacity to be so lucky. Moreover, even if the probability that a creator would produce any given contribution were only around 1/25, the probability of that same creator producing *some* notable contribution would be high. On the average, after a little more than two dozen trials the odds would favor the creator "chancing" upon some major discovery or invention.

A chance model with the parameters of $n = 25$ and $p = 1/25$ could also be compatible with a zeitgeist explanation with some amendments in its traditional posture. If the spirit of the times is influential, then certainly we would expect that the course of scientific

progress would not depend on just one individual. And the existence of more than two dozen potenial contributors for any given discovery or invention obviously would provide the needed reserves. On the other hand, zeitgeist theory must relinquish the idea that discoveries or inventions are inevitable. Under the current parameters more than one-third of all potential contributions will be missed by all. Nonetheless, matters could be a lot worse: The mean could be much smaller than unity, so that the proportion of total failures could exceed half or more. As it stands, with a mean approaching 1, contributions are made once on the average. By permitting multiples to compensate for complete misses, discovery and invention can be said to have at least a probabilistic variety of inevitability.

In conclusion, after various mutual concessions all three perspectives can be said to enhance our overall understanding of multiples. A small group of highly productive individuals are most likely to participate in multiples, including independent rediscoveries. These same geniuses, as it were, are also unusually intimate with the technoscientific zeitgeist and are perhaps equally gifted with an inordinate amount of good luck.

Value Correlates of Conservatism

N. T. Feather
The Flinders University of South Australia, Bedford Park, Australia

Stepwise multiple regression analyses that involved measures of value importance, age, sex, education, and income as the independent variables were conducted to discover the major predictors of conservatism. On the basis of past discussions of the ideal conservative, it was hypothesized that conservative people would emphasize values concerned with attachment to rules and authority and ego defense (e.g., security, cleanliness, obedience, politeness, and salvation) and downgrade other values concerned with equality, freedom, love, and pleasure, as well as open-minded, intellectual, and imaginative modes of thought. This hypothesis was confirmed by the results from two independent surveys involving a sample of families in metropolitan Adelaide (Sample 1, 1972) and the families of a sample of students at Flinders University (Sample 2, 1976/1977). Respondents in both samples answered the Rokeach Value Survey and the Wilson and Patterson Conservatism Scale and provided background and demographic information. In addition to the values, age and sex were significant predictors (especially age), with older respondents tending to be more conservative than younger ones and females more conservative than males. Education and income of the heads (Sample 1) and fathers (Sample 2) of families played a minor role in prediction. Results are interpreted as supporting both the cognitive learning and psychodynamic explanations of value/attitude relationships. The need for developmental studies in this area using new sophisticated methodologies along with causal models is emphasized.

Does the person who has conservative views over a wide range of issues have a different pattern of values from the person whose attitudes are more liberal? The present article reports research that was designed to answer this question. For present purposes conservatism will be defined by reference to the analysis by Wilson and his colleagues (Wilson, 1973). Wilson (1973) claims that conservatism is "a general factor underlying the entire field of social attitudes much the same as intelligence is conceived as a general factor which partly determines abilities in different areas" (p. 3). The "ideal" conservative is seen as a person who tends to have a fundamentalist religious orientation and whose political leanings are likely to be proestablishment and supportive of the status quo; who tends to insist upon strict rules and punishments; who is likely to favor militarism; who tends to be ethnocentric and intolerant of minority groups; who tends to prefer what is conventional, traditional, and familiar; who is likely to be antihedonistic in outlook and to favor restriction of sexual behavior; who tends to oppose scientific progress and "new-fangled" ideas; and who is likely to be fatalistic and superstitious.

Wilson and his colleagues have used a questionnaire, the Conservatism Scale (C Scale), to measure general conservatism. This scale involves items that were selected to relate to the main characteristics of the ideal conservative that have just been mentioned. Each item consists of a word or phrase representing a familiar or controversial issue (e.g., legalized abortion, death penalty, Bible

This research was funded by grants from the Australian Research Grants Committee and from Flinders University.

truth), and the respondent registers approval, disapproval, or uncertainty. This simple item format is assumed to overcome many of the problems inherent in more traditional item formats employing attitude statements.

Wilson (1973, chaps. 4 & 5) draws upon factor analytic evidence in support of his claim that the C Scale measures a general factor called conservatism.[1] One should note, however, that his claim has not, as far as the C Scale is concerned, gone undisputed (Boshier, 1972; Robertson & Cochrane, 1973 —but see also Kirton, 1978; Wilson, 1972). The issue of the structure of conservatism is controversial and complex and is unlikely to be resolved on the basis of factor analytic findings alone (Feather, 1975a). It is clearly necessary to develop theories about the nature of general conservatism and its behavioral correlates and about how conservative attitudes develop. Then one can proceed to test these theories by using a wide range of empirical procedures.

Wilson's own theoretical stance vis-à-vis the conservative attitude syndrome is that it is intimately related to genetic and environmental factors that determine feelings of insecurity and inferiority. The common basis for all of the various components of the syndrome is assumed to be "a generalized susceptibility to experiencing threat or anxiety in the face of uncertainty" (Wilson, 1973, chap. 17). The conservative individual tends to avoid both stimulus and response uncertainty, and this avoidance is reflected in the verbal attitudes that are expressed as well as in other aspects of behavior. Conservative attitudes are therefore assumed by Wilson (1973) to

> . . . serve a defensive function. They arise as a means of simplifying, ordering, controlling, and rendering more secure, both the *external* world (through perceptual processes, stimulus preferences, etc.) and the *internal* world (needs, feelings, desires, etc.). Order is imposed upon inner needs and feelings by subjugating them to rigid and simplistic external codes of conduct (rules, laws, morals, duties, obligations, etc.), thus reducing conflict and averting the anxiety that would accompany awareness of the freedom to choose among alternative modes of action. (pp. 261–264)

These ideas are not dissimilar to those involved in the earlier influential research into the authoritarian personality (Adorno, Frenkel-Brunswik, Levinson, & Sanford, 1950; Kirscht & Dillehay, 1967; Ray, 1973; Sanford, 1973)—for example, in the emphasis upon the defensive functions of conservative attitudes—although Wilson's analysis of conservatism stresses order and control as a means of reducing anxieties relating to feelings of insecurity and inferiority, whereas the theoretical account of authoritarianism draws upon Freudian concepts and deals more with the control of impulses that may be personally and socially unacceptable, such as sex and aggression. Sanford's (1973) recent overview of research into the authoritarian personality impresses with its subtle awareness of the complex personality processes that may underly authoritarian attitudes and the important role played by the family and the wider social context. It is noteworthy, however, that the main personality dispositions of the authoritarian as described by Sanford (1973, pp. 143–146) overlap with the characteristics of the ideal conservative that were previously listed. Descriptively, therefore, the concept of conservatism as employed by Wilson has much in common with the earlier concept of authoritarianism. And at the level of explanation, there is some agreement also that these attitude syndromes may serve the function of ego defense.

In the present article we make no attempt to develop a theory about the structure and dynamics of conservatism. Rather our main interest is to discover whether conservative attitudes are related in predictable ways to more general values. Very little is known about these relationships, but it is reasonable to expect that attitude–value linkages will occur and that their emergence will depend upon the individual's developing ability to form abstract concepts that capture the

[1] For example, a principal-components analysis of the C Scale yielded a first unrotated factor that accounted for much more of the total variance (18.67 percent) than did subsequent factors and that involved a wide variety of items from different content areas (e.g., race, religion, and sex). The high loading items were approximately equally divided as to direction of scoring for conservatism, suggesting that the factor could not be interpreted in terms of response set. Moreover, loadings on the first factor were very similar to the item–whole correlations.

regularities or consistencies in experience, an ability that improves with increasing maturity. It is likely that specific attitudes come first and that general values begin only later to emerge as abstractions from personal experience, especially experience of one's own attitudes and actions, their relationship to the attitudes and behaviors of significant others, and the judgments of significant others about what is and what is not desirable. In time these values become organized into value systems according to their relative importance. Once formed, values and value systems serve as frames of reference or criteria that may be used to guide thought and action in many different contexts. They represent a personal working over of experience in terms of the individual's own internal cognitive capacities and personality dynamics. They may be modified and refined in light of new and discrepant experience, but throughout life they remain as important components of the self-concept. These points have been discussed and elaborated in previous publications (Feather, 1975b, 1978, in press; Rokeach, 1973).

What are some of the values that one would expect to be associated with the conservative attitude syndrome? The previous discussion suggests that values that are commonly held to involve ego defense would be involved. Rokeach (1973, p. 16) singles out a number of them. Research on the authoritarian personality and on religion, he argues, suggests that an overemphasis "on such modes of conduct as cleanliness and politeness and on such end-states as family and national security may be especially helpful to ego defense" (p. 16) and that "religious values more often than not serve ego-defensive functions" (p. 16). At the same time, Rokeach (1973) recognizes that the motivational base of values is complex and that in the final analysis "all of a person's values are conceived to maintain and enhance the master sentiment of self-regard—by helping a person adjust to reality, defend his ego against threat, and test reality" (p. 15).

The values mentioned by Rokeach are contained in his Value Survey, a test that lists 18 terminal values (concerned with goals or end states of existence) and 18 instrumental values (concerned with means or modes of conduct). There are other values from these lists, however, in addition to those related to ego defense, that one would expect to be associated with general conservatism. Thus, a conservative tendency to overglorify authority, rules, and punishment would probably be associated with a more extreme emphasis upon such instrumental values as being obedient and polite and with a downgrading of terminal values such as equality and freedom. Strict adherence to the familiar, the traditional, and the conventional, as demonstrated, for example, in anti-intellectual and antiscientific biases, would probably be associated with diminished importance attached to such instrumental values as being broadminded, imaginative, intellectual, and logical. It is likely that the antihedonistic attitudes assumed to be characteristic of the ideal conservative would be associated with downgrading such terminal values as mature love and pleasure. Finally, the ethnocentric bias of the ideal conservative might appear in an upgrading of cleanliness values and a downgrading of equalitarian values.

In summary, it was predicted that general conservatism as measured by the C Scale would be associated with a more extreme emphasis upon values concerning salvation, security, cleanliness, and obedience, and a less extreme emphasis upon values concerning equality, freedom, pleasure, love, and modes of conduct that involve acting and thinking in broadminded, imaginative, intellectual, and logical ways. These predictions are all consistent with the descriptive and theoretical accounts of conservatism and authoritarianism that were mentioned previously and that have been extensively discussed by others (e.g., Kirscht & Dillehay, 1967; Sanford, 1973; Wilson, 1973).

In addition to providing evidence relating to these predicted relationships, the present study also included background and demographic variables (age, sex, education, income) in the analysis with a view to investigating their relationships to conservatism as well. It is already known that conservatism as measured by the C Scale tends to increase with age and to be higher for females (Feather, 1975b, 1977b; Wilson, 1973). The relationship of conservatism to socioeconomic status is, however, less clear. In a recent

study of the structure of social attitudes, Eysenck (1975) presented evidence for two conservatism factors—general conservative versus radical ideology and socioeconomic conservatism versus socialism—in addition to the tough-mindedness versus tender-mindedness dimension that appeared in his earlier work (Eysenck, 1954). He found that middle-class people tended to be more radical in their general attitudes but more conservative in their economic attitudes when compared with working-class people (see also Lipset, 1960). These results suggest that C Scale scores should tend to decrease with increased level of education, given the fact that the C Scale appears to be measuring the type of general conservatism factor to which Eysenck refers.[2] Thus, it was further predicted that general conservatism will not only increase with age and be higher for females than for males but will also be lower for higher levels of education.

A final aim of the present study was to discover the most important value predictors of general conservatism by using stepwise multiple regression procedures and to compare the level of prediction achieved by these values with that achieved by the values, the background, and demographic variables taken together, and with that achieved by the background and demographic variables alone. Such a comparative analysis does not involve prior specification of a causal model, but it does throw light on the question as to whether information about a person's value priorities provides better prediction of general conservatism than information about age, sex, education, and income and whether information about both sets of variables (values plus background and demographic information) yields an even better result. One can then determine just how much is added by each set of variables when they are included in the predictive equation. The analysis has theoretical significance in that it provides a rough clue as to whether the relationships between value priorities and general conservatism are simply the products of socialization and other experiences associated with age, sex, and socioeconomic status or whether these relationships are more complexly determined and involve not only the molding effect of experience in particular situations but also the operation of internal personality dynamics that affect the way environmental input is coded and transformed (see Sanford, 1973, for a good discussion of this point).

A distinctive feature of the present investigation is that it involved two separate data sets collected at different times with different samples. Hence it was possible to discover how far results with one sample were replicated by the results of the other sample.

Method

Subjects and Procedure

Sample 1 (Adelaide metropolitan). The data for this sample were obtained from an extensive family survey conducted in metropolitan Adelaide in 1972. Details about subjects and procedure have been presented previously (Feather, 1975b, pp. 121–125; 1978). The survey involved dwellings that included children 14 years of age or more. The sample was selected by using a multistage cluster sampling frame of the Adelaide Statistical Division maintained by the School of Social Sciences at Flinders University. An attempt was made to survey all adult members in each dwelling, including children 14 years of age or older. A trained interviewer conducted the survey. Respondents were assured that their answers would be confidential, and names were not required on the questionnaire. They were requested to complete the questionnaire independently, without discussing it with other members of the family. Out of a total of 659 possible respondents from the dwellings sampled, there were 72 refusals, leaving 587 respondents who answered some or all of the complete survey questionnaire (an 89% response rate). These respondents were made up of 147 who described themselves as heads of household (117 male, 30 female), 145 wives, 152 sons, 126 daughters, and 17 from other members of the dwellings.

Sample 2 (Flinders University). This sample involved students who were enrolled in a third year (senior) course on social motivation offered at Flinders University in 1976 and again in 1977, together with members of their families when they were available. These students completed a questionnaire containing the relevant measures. The

[2] The factor analytic studies discussed by Wilson (1973) do not provide evidence for a factor of socioeconomic conservatism. However, this may simply reflect an absence of relevant items in the C Scale.

majority of them then took the questionnaire home and administered it to their parents and to siblings who were 14 years of age or older living in the dwelling. A small number of older students administered it to their wives (or husbands) and to those of their children who were 14 years of age or older and were living in the dwelling. It was emphasized that the questionnaires should be answered independently by family members without any consultation with each other and that answers were confidential. Names were not required on the questionnaire. Data were obtained from 358 respondents consisting of 74 fathers, 83 mothers, 92 sons, and 109 daughters. The response rate from available family members was very high, exceeding 90%.

Questionnaire. The first part of the questionnaire was designed to obtain background and demographic information (e.g., status in household, age, sex, birthplace, income, religion, etc.). This was followed by Form D of the Rokeach Value Survey, containing the two sets of terminal and instrumental values. In this version each value with its short definition is printed on a removable gummed label, and the values in each set are presented in alphabetical order. One set of 18 terminal values concerns general goals or end states of existence (e.g., freedom, happiness, salvation, wisdom). The other set of 18 instrumental values concerns modes of conduct (e.g., being broadminded, honest, loving, responsible). Respondents ranked the 18 terminal and then the 18 instrumental values in their "order of importance to *you,* as guiding principles in *your* life," using the standard instructions (Rokeach, 1973, pp. 357–361). Respondents arrived at their final rank orders by rearranging the gummed labels within each value set so that the final rank orders indicated "how you really feel."

As in other studies in the Flinders program (Feather, 1975b, pp. 23–24) the ranks from 1 (most important) to 18 (least important) were transformed to z scores corresponding to a division into 18 equal areas under the normal curve. This transformation was made on the assumption that it would be easier for respondents to discriminate between the relative importance of values at the extremes of the scale than between those ranked in the middle of the scale (see Cohen & Cohen, 1975, p. 265, and Hays, 1967, pp. 35–39, for justification of this procedure). These transformed ranks for the 18 terminal and the 18 instrumental values constituted the measures of value importance for each respondent, and they could range from +1.91 (most important) to −1.91 (least important).

Respondents also completed the Conservatism Scale devised by Wilson and Patterson (1968) and discussed in Wilson (1973, 1975). The C Scale consists of 50 items, and as mentioned previously, each item relates to some familiar or controversial issue or concept (e.g., death penalty, evolution theory, chastity, church authority, colored immigration, disarmament, strict rules, and so forth). Respondents were asked, "Which of the following do you favor or believe in?" and they answered each item by circling *yes, ?,* or *no.* The C Scale is balanced for acquiescence response set, since *yes* answers to *odd*-numbered items are scored to reflect a conservative response and *no* answers a liberal or nonconservative response, whereas *yes* answers to *even*-numbered items are scored to reflect a liberal response and *no* answers a conservative response. Responses to each item were scored in the usual manner (liberal response = 0, ambiguous response = 1, conservative response = 2), so that total conservatism scores could range from 0 to 100 in the direction of increasing conservatism. There were 575 respondents in Sample 1 and 358 respondents in Sample 2 who completed the C Scale.[3]

Form of Analysis

Product–moment correlation coefficients were computed between the transformed rankings for each value and general conservatism as measured by the total score on the C Scale, and between each of the demographic and background variables and this total score. Subsequently, stepwise multiple regression analyses were conducted using the Statistical Package for the Social Sciences (Nie, Hull, Jenkins, Steinbrenner, & Bent, 1975, chap. 20).

In these analyses sex was coded 1 (male) and 2 (female). Education and income were both coded in relation to the nominated head of each household for Sample 1 (the 1972 metropolitan Adelaide family sample) and in relation to the father of the family in Sample 2 (the 1976/1977 Flinders University family sample). The scores obtained were used for all members of that household so as to provide general measures of the socioeconomic status of each family. In Sample 1 education was coded from 1 to 4 using the following categories: primary or elementary school education (1); secondary school education without matriculation (2); matriculated at secondary school and/or obtained trade qualifications (3); tertiary education (4). Income was coded from 1 to 5 using the following categories for reported annual income: less than $2,000 (1); $2,000–$3,999 (2); $4,000–$5,999 (3); $6,000–$7,999 (4); above $8,000 (5). Both education and income levels were higher in Sample 2 than in Sample 1, as might be expected from the nature of the sample and from the fact

[3] Medians of the ranks for each of the terminal and instrumental values and means for the total conservatism scores for Sample 1 are presented for different groups in Feather (1975b). Correlations between value importance and total conservatism with age partialed out are presented in Feather (1977b). Item means for the 50 items from the C Scale for Sample 1 can be found in Feather (1975a, 1977a). Corresponding information for Sample 2 has not yet been published.

Self-controlled	.04	.15**

Note. Because of missing data, the *N*s for the correlations in this table for Sample 1 (metropolitan Adelaide) ranged from 558 to 575 except for education and income, where the *N*s were 457 and 430, respectively. For Sample 2 (Flinders University), the *N*s ranged from 357 to 358 except for education and income, where *N* was 331.
* $p < .05$. ** $p < .01$. *** $p < .001$.

that data were collected some 4 or 5 years after Sample 1 had been surveyed. For example, 27% of fathers in Sample 2 had or were receiving tertiary education, whereas the corresponding percentage for heads of household in Sample 1 was 17%; and 46% of fathers in Sample 2 had incomes greater than $10,000, whereas the corresponding percentage for heads of household in Sample 1 was 7%. Because of these higher levels of education and income in Sample 2 and because of the smaller sample size, it was not feasible to subdivide Sample 2 for education and income by using the Sample 1 categories. Instead, education was coded as follows: secondary school education without matriculation and/or primary or elementary school education (1), matriculated at secondary school and/or obtained trade qualifications and/or tertiary education (2). Income for Sample 2 was coded as follows: below $10,000 (1), above $10,000 (2). It should be noted, therefore, that analyses involving education and income as variables were on safer ground for Sample 1, where it was possible to distinguish more categories and where the sample was more representative of the population at large.

Results

Simple Correlations of Variables With Conservatism

Table 1 presents the product–moment correlations relating each of the independent variables to total conservatism for Sample 1 and Sample 2.

In both samples there were statistically significant positive relationships between total conservatism and the relative importance assigned by respondents to the following values: family security, national security,

salvation, being clean, being honest, being obedient, and being polite. Also, in both samples there were significant negative relationships between total conservatism and the relative importance assigned by respondents to the following values: an exciting life, a world of beauty, equality, freedom, mature love, pleasure, true friendship, being broad-minded, being imaginative, being independent, and being intellectual. The significant relationships were remarkably consistent from sample to sample not only in their direction but also in their magnitude, and the majority of them were predicted in advance.[4]

The correlations for both samples also showed that total conservatism tended to increase with age and to be higher for females than for males. These relationships were also consistent with predictions.

Total conservatism scores were negatively related to the level of education and income of the head of household in Sample 1, supporting predictions. These relationships were not strong, however, even though they were statistically significant. Nor did they occur in Sample 2, probably because this sample was more highly selected (families of Flinders University students) and, as noted before, less differentiated in the categories of education and income that were employed in the analysis.

A small number of significant value/conservatism correlations were not replicated from sample to sample. Some of these may involve the effects of sample differences and some may be chance events. They will not be discussed further.

Table 2
Multiple Correlations (R*s*) *and Proportion of Variance Explained* (R^2) *From Multiple Regression Analyses Predicting Total Conservatism From Age, Sex, Education, and Income*

Independent variable	Sample 1		Sample 2	
	R	R^2	*R*	R^2
Age + sex	.52	.27	.48	.23
Education + income	.14	.02	.02	.00
Age + sex + education + income	.53	.28	.48	.23

Multiple Regression Analyses

The relationships presented in Table 1 are further clarified by the results of the multiple regression analyses presented in Tables 2, 3, 4, and 5.[5]

Table 2 shows that the combination of age, sex, education, and income was able to account for 28% of the variance in conservatism scores in Sample 1 and 23% in Sample 2, with age and sex as the most important predictors (especially age—see Table 1).

At the 10th step of the stepwise solution, the set of terminal values alone accounted for 45% of the variance in conservatism scores in Sample 1 and 53% in Sample 2; the instrumental values alone accounted for 31% of this variance in Sample 1 and 44% in Sample 2 at the 10th step (see Table 3).[6]

The combination of terminal values with age, sex, education, and income accounted for 50% of the variance in conservatism scores in Sample 1 and 59% in Sample 2

[4] The Sample 1 correlations between value importance and total conservatism and between value importance and age presented in Tables 1 and 6 respectively are marginally different from those presented in a related report (Feather, 1977b) because of very slight differences in the *N*s between both analyses due to the fact that the present study used pairwise deletion of missing data.

[5] In the absence of specific hypotheses about curvilinear trends and interaction effects, it was decided to use a linear regression equation without interaction terms. Moreover, given the large number of independent variables for final inclusion in the equation, this seemed to be a reasonable decision. One exception was the inclusion of Age × Sex as an interaction term in an exploratory analysis involving age, sex, and Age × Sex as predictors. Inclusion of this interaction term made virtually no difference to the multiple *R*s for Sample 1 and Sample 2 when compared with the *R*s obtained by using the equation involving age and sex alone.

[6] Results in Tables 3, 4, and 5 are reported for the first 10 steps for ease of comparison. The step beyond which there was no further significant ($p < .05$) step-by-step increase in R^2 is noted, either in the table or in the text. In all of the analyses reported in Tables 2, 3, 4, and 5 the "adjusted" R^2 values were virtually identical to the actual R^2 values (Nie, Hull, Jenkins, Steinbrenner, & Bent, 1975, p. 358).

Note. The standardized regression coefficients (βs) are those obtained at the end of 10 steps in the analysis. An underlined R^2 indicates that there were no statistically significant ($p < .05$) step-by-step increases in R^2 after that step in the analysis.
* $p < .05$. ** $p < .01$.*** $p < .001$.

at the 10th step; the set of instrumental values combined with these four background and demographic variables accounted for 47% of this variance in Sample 1 and 56% in Sample 2 at the 10th step (see Table 4).

The combination of terminal values and instrumental values accounted for 48% of the variance in conservatism scores in Sample 1 and 60% of this variance in Sample 2 at the 10th step (see Table 5). In both samples step-by-step changes in R^2 continued to be statistically significant ($p < .05$) up to the 14th step. For Sample 1, $R = .71$ and $R^2 = .504$ at the 14th step following the addition of *cheerful, true friendship, imaginative,* and *freedom* to the regression equation in that order. For Sample 2, $R = .78$ and $R^2 = .615$ at the 14th step following the addition of *capable, responsible, a sense of accomplishment,* and *polite* to the regression equation, in that order.

Finally, the combination of all 36 values (terminal plus instrumental) with age, sex, education, and income accounted for 55% of the variance in conservatism scores in Sample 1 and 67% of this variance in Sample 2 at the 10th step (see Table 5). In Sample 1, step-by-step changes in R^2 continued to be statistically significant ($p < .05$) up to the 14th step, where $R = .76$ and $R^2 = .570$, following the addition of *a world of beauty, responsible, independent,* and education to the regression equation, in that order. In Sample 2, statistically significant step-by-step increases in R^2 stopped at the 9th step (see Table 5).

The predictor variables that emerged in the early steps of the analyses reported in Tables 3, 4, and 5 were very similar across the two samples, and they tended to occur in much the same order in both samples. For example, *salvation, family security, national security,* and *equality* emerged in that order for both Sample 1 and Sample 2 in the first four steps of the solution for the terminal values presented in Table 3; age, *broad-minded,* and *obedient* emerged in the first three steps of the second set of analyses presented in Table 4 for both Sample 1 and Sample 2; and age, *salvation, broad-minded,* and *obedient* occupied the first four steps of the second set of analyses reported in Table 5 for both samples. The solutions presented in Tables 3, 4, and 5 therefore appear quite robust—there was a high level of replication from sample to sample despite the fact that different populations were involved and the samples were taken 5 years apart.

Finally, the terminal values were slightly better predictors of conservatism than the instrumental values (see Table 3) and prediction throughout was slightly better for Sample 2 than for Sample 1 (see Tables 3, 4, and 5).

Value Importance and Age

In view of the fact that age emerged from the multiple regression analyses as an important predictor of conservatism, it is also of interest to inquire about the degree to which value importance was a function of

age in both samples. Table 6 reports the product–moment correlations of value importance with age for each of the terminal and instrumental values. (Correlations showing the positive relationships between age and conservatism are contained in Table 1.)

Table 6 indicates that in both samples there were statistically significant positive relationships between age and the relative importance assigned by respondents to the following values: family security, national security, self-respect, being clean, and being polite. These values tended to increase in relative importance with increasing age. Also in both samples there were significant negative relationships between age and the relative importance assigned by respondents to the following values: an exciting life, equality, freedom, social recognition, true friendship, being broad-minded, and being imaginative. These values tended to decrease in importance with increasing age.

Thus, Table 6 shows that there were several value/age relationships that were consistent from sample to sample. These changes in value importance with age are of interest in their own right but they will not be discussed in detail—see Feather (1975b, chap. 6) and Feather (in press) for relevant discussion of age differences in values.

There were a small number of significant value/age correlations that were not replicated from sample to sample. Most of these significant relationships occurred in Sample 1, and they may reflect the fact that this sample came from a wider and more hetero-

geneous population than Sample 2. Some of the nonreplicated effects may also be chance events.

Discussion

The results of the present study are clear and consistent. As predicted, conservatism was positively related to the relative importance of values that could be taken to involve ego defense and attachment to authority—values that were concerned with salvation, security, cleanliness, and rule following. The higher the conservatism score, the more likely it was that these values would be emphasized. Also as predicted, conservatism was negatively related to the relative importance of values that referred to equality, freedom, love, and pleasure, as well as open-minded, intellectual, and imaginative ways of thinking. The higher the conservatism score, the less likely it was that these values would be emphasized. Conservatism was also associated with age and sex in the direction predicted. Thus, older people tended to be more conservative than younger people, and females were slightly more conservative than males. Finally, the relative importance of some of the values varied systematically with differences in age. All of these results were replicated from sample to sample and they therefore stand as reliable findings. Moreover the replication indicated that correlations were not only in the same direction in both samples but were also similar in their orders of magnitude.[7]

The results also showed that conservatism was negatively related to the education and income levels of heads of households in Sample 1, though the correlations were relatively small. Higher conservatism tended to

[7] Those with high conservatism scores were also more likely to downgrade values concerned with beauty, excitement, and independence, perhaps again reflecting a preference for convention, tradition, structure, and stability as opposed to novelty, independence, complexity, and change.

Table 6
Product–Moment Correlations (Simple rs) Relating Value Importance to Age for Samples 1 and 2

Note. Because of missing data, the *N*s for the correlations in this table for Sample 1 (metropolitan Adelaide) ranged from 562 to 574. For Sample 2 (Flinders University), the *N*s ranged from 357 to 358.
* $p < .05$. ** $p < .01$. *** $p < .001$.

be associated with lower levels of education and income. However, conservatism was not significantly related to these socioeconomic measures in Sample 2, probably for the reasons presented earlier.

While the present study is essentially descriptive rather than based upon a causal model, the results do advance our knowledge about general conservatism. In the first place, they indicate the values that relate to this attitude syndrome and thereby provide a reliable set of findings to be explained. One can agree with Rokeach (1973) that there is a compelling need to assemble descriptive information about attitude–value relationships while at the same time seeking explanations about how these relationships came about. These explanations are likely to be complex rather than simple, having regard not only to the impact of different social institutions and environments but also to the active, constructive way in which information is processed by individuals according to the structure and dynamics of personality.

Second, the results of the regression analyses do have some implications about likely causal mediators. The fact that certain values emerged as strong predictors of conservatism even when the background and demographic variables were included in the regression equation (see Tables 4 and 5) suggests that the obtained relationships between value priorities and conservatism were mediated by more than social learning and probably also involved the operation of internal personality dynamics that helped shape a system of relatively consistent attitudes and values. Thus, these results can be understood in terms of both the cognitive learning and the psychodynamic explanations of attitude syndromes such as authoritarianism and conservatism that have been discussed by several authors (e.g., Elms, 1976; Greenstein, 1969; Sanford, 1973). These explanations relate authoritarianism and conservatism to learned conceptions of reality and ways of adjustment that are shaped by the actual conditions of a person's life and to intrapsychic determinants involving the expression, satisfaction, and control of basic needs and the operation of complex ego mechanisms that are in the service of the self.

That both kinds of explanation are necessary is especially suggested by the results presented in Tables 4 and 5, where the best set of predictors of general conservatism involved a combination of values and age, with sex and socioeconomic background entering much further down the list. Age is a variable that acquires meaning only in terms of its correlates. Among these correlates are the experiences—some unique, some shared with others—that would determine changes in both value priorities and conservatism over time. Even with age included as a variable in the regression equation, however, certain values remained as important predictors of conservatism, and these values, involving a preference for authority, rules, safety, and religion and a downgrading of equality, love, and open-minded modes of thought, are consistent with past discussions of conservative and authoritarian attitudes and ideologies (e.g., Adorno et al., 1950; Elms, 1976; Greenstein, 1969; Kirscht & Dillehay, 1967; Rokeach, 1960; Sanford, 1973; Tomkins, 1963; Wilson, 1973). In view of the fact that these values emerged as important predictors after age and the other background variables were controlled, it is reasonable to assume that personality dynamics relating to impulse satisfaction and control and their effects on cognition also played an important role in determining the nature of the value/conservatism relationships.

Given the relationships between values and conservatism described in the present study, longitudinal investigations that enable one to separate out cause and effect are needed in the future. It is nearly 30 years since *The Authoritarian Personality* was published (Adorno et al., 1950). One can now improve upon the procedures used in that seminal research in many ways, not least by employing methodologies that have emerged from life span developmental psychology and go beyond simple cross-sectional and single-cohort longitudinal studies in an attempt to discover the complex influences involved (Feather, 1975b, pp. 143–146). These new procedures are costly and time consuming,

but they are essential if one is to disentangle the factors determining change and continuity in values and attitudes over time. Using these improved methodologies, one could design developmental studies that explore the basis for relationships between values and conservative attitudes across the life span and enable the formulation of more sophisticated theoretical analyses.[8]

Not enough is known about the conditions under which general values emerge and how they come to be related to specific attitudes. It is likely that the sequence of events is complex and that attitudes tied to specific objects and issues develop first, followed by the emergence of general values as abstractions from the welter of a person's experience as it reflects the attitudes and actions both of self and of significant others (see Adelson, 1975; Feather, 1978, in press). Once formed, the dominant values may then inform a person regarding the correct attitudes toward new objects and issues. The hierarchy of values would itself change over the life span, some values increasing in relative importance and others decreasing. And new beliefs and attitudes would also be acquired, concomitant with these general changes and based upon similar causes. This new learning, along with the modifications in the value hierarchy, would not only reflect the inevitable changes that occur across the life span as people grow older, take on new roles and responsibilities, and develop new needs and priorities as they cope with a changing biology and the altered circumstances of their lives; they would also be influenced by general social trends and unique historical events (Feather, 1975b; 1977a; in press). With change in the hierarchy of a person's values and the formation of new beliefs and attitudes, one would also expect to find alteration in some of the more specific orientations laid down in the past, so that the total set of beliefs, attitudes, and values forms a relatively consistent and interrelated system in general harmony with a person's overall self-concept. All of these matters are of obvious relevance to clarifying the basis of the relationships between values and conservatism and deserve detailed investigation in the future.

The results of the present study indicate which values such studies might focus upon. One can agree with Rokeach (1973) that freedom and equality are two terminal values of special significance in the analysis of differences in *political* conservatism. Indeed, for a number of reasons, Rokeach (1973, pp. 165–170) doubts the usefulness of employing a single continuum of liberalism–conservatism, preferring instead to refer to variations in political ideologies that can be defined by differences in the relative importance assigned to the two terminal values freedom and equality. In terms of his two-value model of political ideology (Rokeach, 1973, p. 170), high scorers on the C Scale could be seen as more likely to demonstrate a "profascist" ideology (freedom low, equality low) and low scorers a "prosocialist" ideology (freedom high, equality high), given the fact that total conservatism scores were negatively correlated with the relative importance assigned to both freedom and equality on the Value Survey (see Table 1). The present results show, however, that several other values were associated with general conservatism as defined by the C Scale, and these deserve future investigation also, along with further clarification of the concept of conservatism and the extent to which it is unitary or multidimensional.

---

[8] For an excellent recent example in which these new methodologies have been applied to the study of political orientations, see Jennings and Niemi (1975).

The culminating statement of 50 years research in personality!

PERSONALITY AND LEARNING THEORY (2 Vols.)

Raymond B. Cattell, Ph.D., D. Sc.

Vol. 1 The Structure of Personality in Its Environment

Here is the first substantial synthesis linking the study of personality with the control tenets of learning theory. Through multivariate experimental methods Cattell has devised a system by which personality can be captured with mathematical models that operationalize theories of personality structure. Volume 1 relates personality, ability, dynamic traits and states to the dimensions of stimuli, environmental situation, and observer.

This first volume integrates the work of a hundred different researchers, raising statistical and structural concepts of traits, types, and processes to a new level of precision. Using original conceptual developments on integrated and unintegrated motivation measurement, conflict theory, the dynamic lattice, and emotional decision theory, Cattell reexamines and refines known dynamic traits. He includes discussions on trait and perturbation theory, laws of error, psychological relativity, observer distortion, and instrument factors. Volume 1 treats with unusual thoroughness the recently focussed problem of proper incorporation of situation, observer, and other aspects of the environment in personality prediction.

The unique feature of this treatise on personality, at this juncture in psychology, is the completeness of Cattell's theoretical model which presents an embracing and consistent theory of personality and its actions. The first volume will provide a challenging text in graduate courses in personality and an ideal supplement to any graduate course in psychometry.

Vol. **2 A Systems Theory of Maturation and Structured Learning** will be available from Springer in 1980. This two volume work is a landmark of scholarship in psychology.

Vol. 1: 448 pp. 1979 $29.00 hardcover

Cognitive Orientation and Behavior

Hans Kreitler, Ph.D. and Shulamith Kreitler, Ph. D.

Presents a theory of cognitive orientation that describes the chain of cognitive processes from input identification to intent and behavior. This theory provides a model for reliable prediction and modification of behavior. The theory and methods of cognitive orientation are equally pertinent for the practitioner and the researcher in clinical, educational, and social psychology.

"...a great service in showing...that a cognitive psychology is really plausible, but also... leads to a lot of interesting research, which they report." *– David C. McClelland*

447 pp. 1976 $27.50 hard

Family Constellation

Its Effect on Personality and Social Behavior, 3rd. Ed.

Walter Toman, Ph.D.

Completely rewritten, and with expanded research evidence, this well-known book describes how sibling position influences personality and shapes the individual's relationships within and outside the family.

344 pp. 1976 $15.50 hard $8.95 soft

Personality Changes in Aging

A Longitudinal Study of Community Residents

Joseph H. Britton, Ph.D. and Jean O. Britton, Ph.D.

Based on nine years intensive research, the book sheds light on the different rates at which individuals decline with advancing years.

236 pp. 1972 $9.50 hard

Who Will Marry Whom?

Theories and Research in Marital Choice

Bernard I. Murstein, Ph.D.

"Significant insights into the innumerable variables that could potentially influence marital choice."

– J. of Personality Assessment

392 pp. 1976 $17.95 hard

The Journal Supplement Abstract Service is an information service providing ready access to psychology-related materials not available through conventional communication channels.

JSAS Selects and Disseminates:

- Educational materials
- Massive data collections
- Methodological techniques and procedures
- Major projects in progress
- Descriptions of effective techniques or programs
- Technical reports
- Fresh looks at controversial issues
- Invited lectures
- Management of psychological resources
- APA task force reports
- Bibliographies
- Literature reviews

Manuscripts are accepted by a panel of editors. They meet the same high standards set for American Psychological Association's journals, but are not bound by conventional restrictions of format, length, or editorial policy.

Available titles are listed in the quarterly JSAS *Catalog of Selected Documents in Psychology*. The catalog includes abstracts of newly accepted manuscripts along with manuscript length, price, and ordering information. Each issue of the catalog contains about 50 abstracts. Full-text manuscripts may be purchased individually in paper or microfiche.

Subscription rates for the quarterly catalog are $6 for APA members and $14 for nonmembers (foreign, $16). Please include full remittance for orders of $25 or less. To order, make check payable to APA and mail to:

SOCIAL EXCHANGE IN DEVELOPING RELATIONSHIPS

Edited by ROBERT L. BURGESS and TED L. HUSTON

FROM THE PREFACE: Our intent in preparing this book was to encourage the systematic study of the development of relationships. Throughout, several theoretical perspectives are presented, including evolutionary theory, cognitive developmental theory, personality theory, role theory, equity theory, and attribution theory. In each case, however, the authors address the issue of exchange in developing relations. Their views of the exchange process differ as a function of their own theoretical perspectives. Such is the state of the art. . . .

SECTION HEADINGS: Introduction. The Developmental Course of Close Relationships. Beyond the Dyad: Approaches to Explaining Exchange in Developing Relationships. Epilogue. References are included at the end of each chapter.

1979, 432 pp., $24.00 ISBN: 0-12-143550-4

ROLE THEORY: Expectations, Identities, and Behaviors

By BRUCE J. BIDDLE

FROM THE PREFACE: This book constitutes an integrative exposition of role theory. As is well known, the role perspective arose coincidentally in several disciplines in the late 1920's and early 1930's. Its central concern has been with patterns of human conduct—*roles;* with expectations, identities, and social positions; and with context and social structure as well as with individual response. As such, role theory offers a perspective that bridges social psychology, sociology, and anthropology. Thus, it has generated interest among social scientists from many backgrounds.

This work provides a long-needed synthesis for role theory. A single overarching conceptual system is set for the role field which embraces other uses. Research involving role concepts is reviewed. Applications of role concepts are discussed for education, social work, and clinical practice. Advantages and shortcomings of the role stance are examined.

1979, 380 pp., $19.50 ISBN: 0-12-095950-X

FOUNDATIONS OF DIALECTICAL PSYCHOLOGY

By KLAUS RIEGEL

CHAPTER HEADINGS: The Dialectics of Human Development. Historical Introduction. Dialectical Operations: The First and Final Period of Cognitive Development. The Relational Basis of Language. The Temporal Organization of Dialogues. The Recollection of the Individual and Collective Past. Adult Life Crises. The Dialectics of Time. References. Author Index. Subject Index.

1979, 216 pp., $15.00 ISBN: 0-12-588080-4

The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1976 issue (Vol. 33, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts according to instructions on p. 1439 of the August issue.

Required supplementary information: Manuscripts cannot be reviewed for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author(s) that are currently submitted, in press, or recently published; (b) one copy of each such related paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the *major* analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restaint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics, except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1400 North Uhle Street, Arlington, Virginia 22201. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

University of Texas at Austin

In a conceptual replication and extension of a study by Bem and Lenney, male ($n = 90$) and female ($n = 118$) college students rated their comfort in and preference for performing several series of masculine, feminine, and neutral activities. Correlations between these ratings and scores on the masculinity (instrumentality) and femininity (expressiveness) scales of the Personal Attributes Questionnaire (PAQ) of Spence and Helmreich tended to be theoretically reasonable in sign but in each sex were low in magnitude and only occasionally significant. Classification of subjects into four PAQ groups (androgynous, masculine, feminine, and undifferentiated) on their joint masculinity and femininity scores revealed that androgynous and masculine subjects of both sexes had higher comfort ratings, independent of type of task, than did feminine and undifferentiated subjects, suggesting the importance of instrumentality and expressiveness per se. For forced-choice preference ratings, significant differences were found only in males, masculine subjects having a stronger preference for sex-typed tasks than those in other categorical groups. The PAQ variable, however, accounted for only a small percentage of the variance. The data support the Spence–Helmreich hypothesis that the PAQ and other similar instruments are largely measures of instrumental and expressive personality traits rather than sex roles and that these personality dimensions are only minimally related to many sex role behaviors.

Interest in the concept of psychological androgyny has generated an increasing volume of empirical research, much of it using the Bem Sex Role Inventory (BSRI: Bem, 1974, 1977) or the Personal Attributes Questionnaire (PAQ: Spence & Helmreich, 1978; Spence, Helmreich, & Stapp, 1974, 1975) as the operational measure of the construct. Each of these instruments contains separate masculinity and femininity scales that are essentially orthogonal. The androgynous individual, according to current usage, is defined as one who scores relatively high on both the masculinity (M) and femininity (F) scales of these self-report instruments.

While the developers of the BSRI and the PAQ share certain theoretical assumptions that have guided both their empirical inves-

Research

tigations and their interpretation of the results, their views differ in other critical respects. These differences, in turn, lead to predictions about the behavior of "androgynous" individuals that do not always coincide. The present study, using the PAQ, involved conditions in which the implications of the two theories led to different expectations. In order to explain its rationale, it is first necessary to describe the empirical properties of both the PAQ and the BSRI.

The PAQ M scale consists of a series of descriptions of traits, each stereotypically more characteristic of men than women but socially desirable to some degree in both sexes. Similarly, the F scale consists of descriptions of socially desirable traits more characteristic of women. In content, the trait clusters reflect what Parsons and Bales (1955) have described as instrumental (masculine) and expressive (feminine) characteristics. Factor analyses of the PAQ reproduce the two empirically derived scales, thus adding further justification to their separation (Spence & Helmreich, 1979; Helmreich, Spence, & Wilhelm, in press). The scales have been demonstrated to discriminate between the sexes in diverse populations, varying widely in age, ethnicity, and social class (e.g., Spence & Helmreich, 1978), thus justifying use of the labels *masculinity* and *femininity*.

In sum, the PAQ is a quite conventional self-report measure of socioaffective instrumental and expressive traits, the items making no mention of instrumental or expressive behaviors or the situations that elicit them. These trait dimensions, according to our theoretical conception, are internally located response predispositions that combine with situational variables and other person variables to determine behavior but are not themselves identical to behavior.

Of the evidence that has been collected to support the construct validity of the PAQ scales as measures of instrumentality and expressiveness, a recent experiment by Klein (Note 1) is particularly instructive. Klein observed the dominance behavior of female college students in three-member problem-solving groups, two members of which were the experimenter's confederates. Subjects' scores on the PAQ M scale were positively correlated with degree of dominance behavior, whereas their scores on the F scale showed a slight negative correlation with this behavior. As might be expected from these correlations, masculine women (high in M, low in F) were most dominant, followed in order by women who were androgynous (high M, high F), feminine (low M, high F), and undifferentiated (low M, low F). This order was found both when the two confederates were female and when they were male. In all PAQ groups, however, level of dominance was markedly (and equally) reduced when the two confederates were male, a condition containing implicit role-related constraints on women's undisguised expression of this type of behavior. The results thus show that situational factors (presence or absence of sex role expectations) and personality traits (M and F) independently contributed to dominance behavior.

Like the PAQ, the BSRI consists of general trait descriptions, many of the M items being socially desirable instrumental traits and many of the F items being socially desirable expressive traits that are similar or identical to PAQ items on the parallel scales. However, not all items on the BSRI can be described as instrumental or expressive (e.g., "masculine" and "feminine") or (on the F scale) as socially desirable, and unlike the PAQ, recent factor analytic studies (e.g., Pedhazur & Tetenbaum, 1979) indicate a four- rather than a two-factor structure. Nonetheless, empirical evidence supporting the construct validity of the BSRI as (primarily) a measure of instrumentality and expressiveness has been found in behavioral studies by Bem and

Support for this research was provided by National Science Foundation Grant BNS 78-08911 (Janet T. Spence and Robert L. Helmreich, Principal Investigators). The paper was prepared while the second author was a Fellow at the Center for Advanced Study in the Behavioral Sciences with support from the Spencer Foundation, National Institute of Mental Health Grant 5T32MH14581-03, and The University of Texas Research Institute.

her colleagues (Bem, 1975, 1977; Bem, Martyna, & Watson, 1976).

The somewhat mixed content of the BSRI, the identification of the instrument as a sex role inventory, and Bem's theoretical discussions combine to suggest that she posits the existence of global constructs of masculinity and femininity that are manifested in a variety of gender-related behaviors, role attitudes, and personal qualities collectively identified as *sex roles*. She further appears to assume that, despite their limited empirical content, the BSRI and PAQ M and F scales are (in principle) valid measures of these global constructs. Thus, according to her conceptualization (e.g., Bem, 1977; Bem & Lenney, 1976), androgynous individuals, high in both M and F scores, are "behaviorally flexible" with respect to all manner of gender-related phenomena. As such, they are willing or able to exhibit masculine behaviors, feminine behaviors, or both, as situationally appropriate. Individuals with sex-typed personalities, on the other hand, will tend to avoid or exhibit lower levels of cross-sex-typed behaviors.

This theoretical position rests on the supposition that the empirically diverse indicators of masculinity and of femininity are all highly correlated, so that an individual exhibiting one set of attributes or behaviors in the class can reasonably be assumed to exhibit approximately the same degree of all other attributes and behaviors. If the subsets of masculine and feminine behaviors, attitudes, and personality characteristics that differentiate the sexes do covary within individuals, then it follows that it is useful to postulate global unidimensional concepts, and further, that it is justifiable to use instruments such as the PAQ or BSRI that tap a limited range of gender-related traits to make inferences about other kinds of masculine and feminine qualities.

Spence and Helmreich (1978) have not denied the existence of associations between various classes of masculine and feminine attributes and behaviors but have proposed that they often are weak and/or complexly determined. More particularly, they hypothesize that socially desirable masculine and feminine (i.e., instrumental and expressive) personality traits are not likely to be strongly related to sex role preferences or behaviors unless these behaviors call quite directly for instrumental or expressive skills. They thus suggest that personality instruments such as the PAQ and the BSRI cannot legitimately be substituted for more face valid measures of sex role attitudes and preferences, and that findings obtained with these personality instruments will not necessarily parallel those with sex role measures. For example, theoretically reasonable but very weak relationships have been found between the PAQ and BSRI M and F scales and the Attitudes Toward Women Scale (AWS: Spence & Helmreich, 1973), a measure of beliefs regarding appropriate roles of women vis-à-vis men (Orlofsky, Astin, & Ginsburg, 1977; Spence & Helmreich, in press). The values, however, are low and often nonsignificant even in very large samples. Similarly, the study by Klein (Note 1) cited earlier suggested that sex-typed (feminine) women, as measured by the PAQ, were no more responsive to the introduction of sex role demands into group interactions than were women showing other personality patterns.

In an experiment that went beyond the investigation of instrumental and expressive behaviors, Bem and Lenney (1976) tested the behavioral flexibility hypothesis by examining the relationship between masculine and feminine traits, as measured by the BSRI, and reactions to gender-related activities. Male and female subjects were asked to demonstrate a series of simple tasks (e.g., pounding a nail in a board) that were stereotypically masculine or feminine and then to indicate their degree of comfort in performing them. Prior to this portion of the study, they were given a description of a series of pairs of tasks, each pair consisting of either two neutral tasks or a masculine and a feminine task, and were asked to indicate which they preferred to demonstrate. Three groups of male and female subjects, designated as *masculine*, *feminine*, and *androgynous*, were preselected to serve in the experiment, assignment of subject to group being based on Bem's (1974) original subtractive (F

minus M) method of scoring the BSRI. Subjects were chosen from the center and the two extremes of the difference score distribution. The results partially supported the behavioral flexibility hypothesis, heavily sex-typed individuals (masculine men, feminine women) tending to show more avoidance of cross-typed tasks than did the other groups. Androgynous (balanced) subjects, however, did not differ significantly from cross-typed subjects.

The present study is a conceptual replication and extension of the Bem and Lenney study, using the PAQ rather than the BSRI. Male and female students, pretested on the PAQ and later given the Attitudes Toward Women Scale (Spence & Helmreich, 1973), were told that they would be asked to demonstrate several activities from a larger group and could indicate their preference beforehand. They were given two lists, each containing stereotypically masculine, feminine, and sex-neutral activities. The first list consisted of simple, everyday tasks similar to those used by Bem and Lenney (1976). The second list contained descriptions of TV commercials or public service announcements, half of which were affectively neutral and half negatively toned. In including a number of tasks that were mildly embarrassing or distasteful, we were exploring the possibility that stronger relationships might be found between reactions to negative items and the PAQ scales than those involving affectively neutral items. Two types of ratings were obtained. For each item, subjects were asked to indicate the degree of anticipated comfort in performing the named activity. They were also asked to give preference ratings within the groups of everyday tasks, affectively neutral announcements, and negative announcements. Subjects were unselected with respect to PAQ and AWS scores, thus permitting assessment of both the independent and joint effects of M, F, and AWS scores on the criterion measures as well as the magnitude of effects.

In deriving hypotheses about the results from Bem's work, several aspects of her theory and the Bem and Lenney study should first be noted. First, in response to data (Spence et al., 1975) indicating that a scoring scheme taking into account absolute level of M and F scores has greater utility than does a subtractive method, Bem (1977) subsequently revised her definition of androgyny to refer only to those relatively *high* in M and F. She also adopted the Spence et al. designation of undifferentiated to refer to those relatively *low* in M and F. Second, in discussing evidence bearing on the hypothesis that androgynous (high M, high F) individuals are more "behaviorally flexible" than others, Bem and others have seemed to treat the type of sex role behavior studied by Bem and Lenney as having equal standing with behaviors demanding the expression of instrumental or expressive qualities. That is, responses to the types of gender-related tasks employed by Bem and Lenney are implicitly regarded as being in the same class as instrumental or expressive behaviors and are therefore implied to be related to the BSRI in the same manner and with the same strength as instrumental and expressive behaviors. There is both an internal contradiction and incompleteness in her theory, however. Although the experimental evidence (e.g., Bem et al., 1976, as reanalyzed in Bem, 1977) indicates that androgynous and undifferentiated individuals are not identical in behaviors designed to reflect instrumental or expressive capacities, Bem (1977) has stated that she would expect *no* differences between those groups on the types of tasks employed by Bem and Lenney. (Presumably undifferentiated individuals, being neither strongly masculine nor strongly feminine in their "sex-role identification," would show little differential reaction to sex-linked tasks.) Thus, on *this type of task*, undifferentiated and androgynous groups are *both* expected to be more "behaviorally flexible" than sex-typed individuals. More specifically, her theory predicts that androgynous and undifferentiated groups, male and female, will not differ from each other but that both categorical groups will show less marked preference for same-sex tasks and will express more comfort about performing opposite-sex tasks than will sex-typed individuals (masculine men, feminine women). Bem is unclear about what to expect in cross-typed individ-

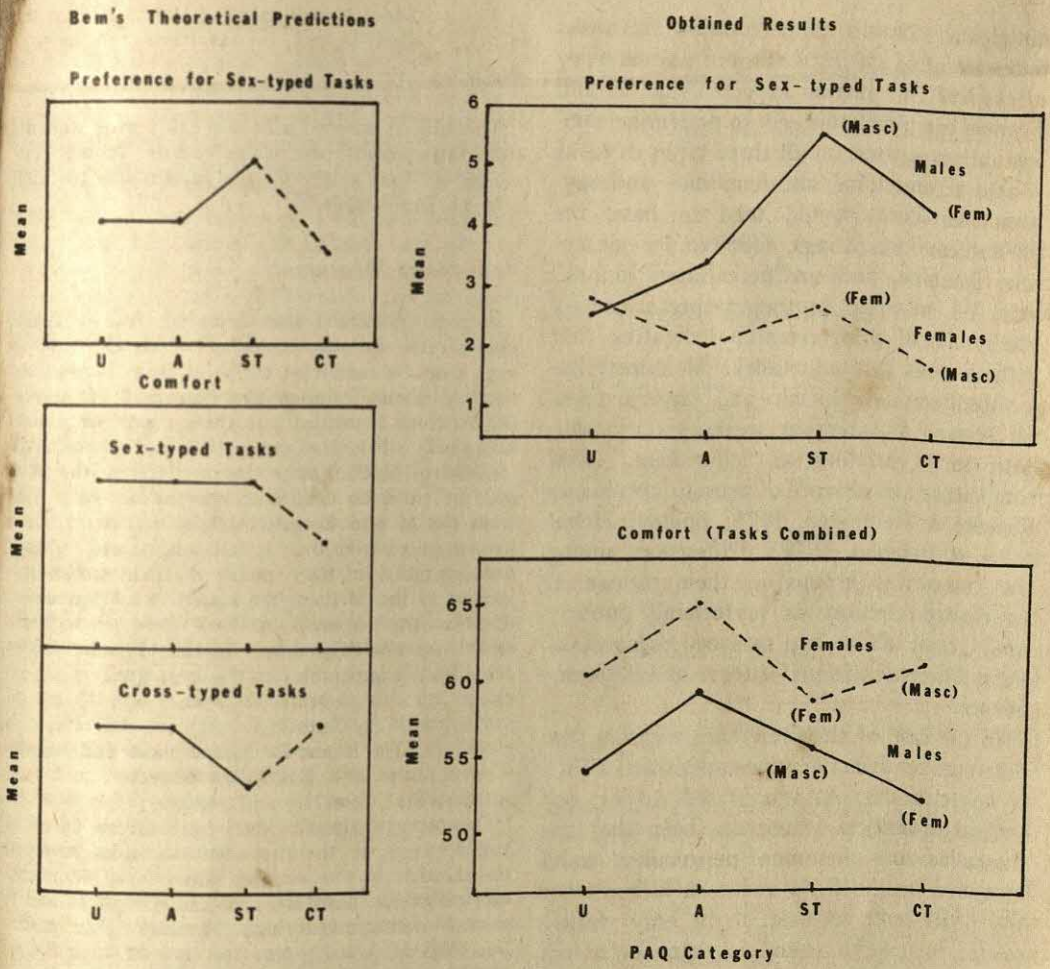

Figure 1. Predicted mean sex-typed preference and comfort ratings (Bem's hypotheses) in undifferentiated, androgynous, sex-typed, and cross-typed groups and obtained means for males and females in the groups. (U = undifferentiated; A = androgynous; ST = sex-typed [masculine male, feminine female]; CT = cross-typed [feminine male, masculine female]. The predicted preference and comfort ratings show the expected order of means. They do not reflect predicted magnitudes of effects. PAQ = Personal Attributes Questionnaire. Masc. = masculine. Fem. = feminine.)

uals (feminine men, masculine women). It would seem to follow from an extension of her logic, however, that these groups would also be less flexible than undifferentiated and androgynous groups, showing the mirror image in their preferences and comfort ratings of same- and opposite-sex tasks as masculine men and feminine women. The implications of these hypotheses for both comfort and preference ratings are shown graphically at the left of Figure 1.

These hypotheses, which also imply fairly substantial relationships between the PAQ scales and preferences for and comfort in performing sex-typed tasks, are to be contrasted with the expectations of the present investigators. We anticipated that while subjects' gender would be a major determinant of their reactions to sex-typed tasks (a point on which Bem is silent), the relationships within each sex between M and F and the criterion measures would be minimal and/or of a different form than predicted by Bem. More specifically, we expected that M scores, and to a lesser degree F scores, would be weakly but positively related to subjects' ratings of their

anticipated comfort in performing the tasks *independent of subjects' sex and the category of the task*. We further expected that M and F would combine additively to determine comfort ratings so that on all three types of tasks —neutral, masculine, and feminine—androgynous individuals would tend to have the highest comfort ratings, followed by masculine, feminine, and undifferentiated individuals. We were led to these expectations by the results of prior research indicating that in both sexes instrumentality (M scores) has a substantial relationship and expressiveness (F scores) a somewhat weaker relationship with such variables as self-esteem, social competence and absence of neurotic tendencies (Spence & Helmreich, 1978; Spence, Helmreich, & Holahan, 1979). Differences among the categorical groups in their ratings of anticipated comfort in performing publicly would come about, we reasoned, because of their differences in self-esteem and self-confidence.

In the case of the preference measure, the difference between our expectations and Bem's is less clear-cut. As was stated earlier, our general theoretical stance has been that the masculine and feminine personality traits measured by the PAQ and to a large extent the BSRI tend, at best, to be only weakly related to masculine and feminine behaviors and characteristics that do not directly implicate instrumentality and expressiveness. On a forced-choice preference measure, it seemed possible that *some* correlation might be found between M and F scores and preference scores, M being related positively and F negatively to preference for stereotypically masculine over stereotypically feminine tasks. These relationships were expected to be somewhat stronger in males than in females because of the greater pressures males experience for sex role conformity. Even in the case of males, however, we anticipated that the relationships would be weak, PAQ scores accounting for a small portion of the variance within each sex. We expected a stronger relationship, however, between preference rating and scores on our sex role attitudes measure (AWS), again, especially in males.

Method

Subjects

The subjects were 90 male and 118 female students from introductory psychology courses at the University of Texas at Austin who participated to fulfill a course requirement.

Assessment Measures

Personal Attributes Questionnaire. At the beginning of the semester, classes of which the subjects were members completed the short form of the Personal Attributes Questionnaire (Spence & Helmreich, 1978), which is divided into three eight-item scales: masculinity (M), femininity (F), and masculinity-femininity (M–F). (Since the results from the M–F scale provided no additional information, only data from the M and F scales will be reported.) Each item is scored from 0 to 4, and total scores for each scale are obtained by summing the item scores. Responses to the M items are scored in a "masculine" direction and responses to the F items in a "feminine" direction. The means on the M and F scales are highly comparable to the normative data for college students presented in Spence and Helmreich (1978), with significant ($p < .01$) sex differences on each scale. The means for M for males and females were 21.6 and 20.0. For F, the respective male and female means were 21.9 and 24.4.

One of the analyses of the joint contribution of M and F scores to the dependent variables involved classification of the subjects into one of four categorical groups, based on a median split of M and F scores: androgynous (high M, high F), masculine (high M, low F), feminine (low M, high F), or undifferentiated (low M, low F). The median scores, taken from norms for male and female college students (Spence & Helmreich, 1978), were 21 for the M scale and 23 for the F scale. The percentage of males and females in each of the four categories again closely paralleled the normative data in Spence and Helmreich (1978, p. 53). The breakdowns for males and females, respectively, were: androgynous, 30% and 32%; masculine, 33% and 13%; feminine, 13% and 31%; and undifferentiated, 21% and 24%.

Attitudes Toward Women Scale. At the conclusion of the testing session, subjects completed the 15-item form of the Attitudes Toward Women Scale (Spence & Helmreich, 1978), a questionnaire inquiring about the rights, roles, and privileges that women ought to have or be permitted. Respondents are asked to indicate their agreement with each statement on a 4-point scale ranging from *strongly agree* to *strongly disagree*. Items are scored 0–3, with high scores indicating more profeminist attitudes. A total score is obtained by summing the 15 item scores. Consistent with previous research, women subjects scored as significantly more liberal on the AWS ($p < .001$) and the means of 25.0 for males and 30.1 for females were highly similar to those found in

other college samples (Spence & Helmreich, 1978).

Activities questionnaire. An activities questionnaire was constructed to measure subjects' reactions to performing various masculine, feminine, and neutral activities. Two lists of activities were included. The first, labeled *everyday behaviors,* described a series of simple tasks comparable to those used by Bem and Lenney (1976). These included, in random order, 4 masculine behaviors, 4 feminine behaviors, and 4 neutral behaviors. The 12 tasks were rated by 10 male and 10 female student judges on 5-point scales labeled 1 = very feminine, 3 = non-sex-typed, 5 = very masculine. The results confirmed the adequacy of the classification. Items and mean ratings are shown in Table 1.

Subjects were asked to imagine themselves performing each activity and to indicate on a 7-point scale how comfortable they would be. The scale ranged from *very uncomfortable* to *very comfortable,* with high scores indicating greater comfort.

The second list, labeled *announcements,* was composed of 24 items referring to a TV announcement of public interest or a description of some product. Subjects were asked to imagine themselves reading a prepared message on each of the topics and to rate how comfortable they would feel, again on a 7-point scale. In content, the items were equally divided among masculine, feminine, and sex-neutral topics. Four of the announcements in each of the three categories were affectively neutral (e.g., feminine: "Point out the positive features of a particular style of purse while holding up the purse"). The other four of the activities in each category were somewhat embarrassing or negative in nature (e.g., masculine: "Point out on a model the positive features of a pair of jockey shorts"). The ratings of undergraduate judges also confirmed the assignment of the announcements to the three sex-typed categories. (Assignment to affectively negative and neutral categories was confirmed post hoc by the comfort ratings of the experimental subjects themselves.)

After making their comfort ratings, subjects were asked to indicate their preferences for performing the previously rated activities. The activities were presented in three separate lists. The first contained the 12 everyday behaviors, the second the 12 affectively neutral announcements, and the third the 12 negative announcements. For each list separately, subjects were asked to indicate the 4 activities they would most prefer to perform and the 4 activities they would least prefer to perform. A score of 3 was assigned to items marked as most preferred, a score of 2 to the unmarked items, and a score of 1 to the items marked as least preferred. For each list, each subject's scores for the 4 masculine, feminine, and sex-neutral items were summed to yield preference scores.

Embarrassment index. After demonstrating two tasks from the everyday behaviors list, one masculine and one feminine, subjects were asked to indicate on a 7-point scale how embarrassed they felt while performing each task. Since Bem and Lenney (1976) found that predemonstration ratings yielded as satisfactory results as postdemonstration ratings, this portion of the study was abbreviated and was conducted primarily to protect the cover story about the purpose of obtaining the initial comfort and preference ratings. Further, it was felt that the subjects' relief in not having to give any of the negative announcements might obscure any differential reactions to the masculine and feminine tasks that might otherwise have occurred. In support of this suspicion, an analysis of the embarrassment ratings revealed no significant differences in either sex. For this reason, no further reference will be made to these data.

Table 1
Everday Tasks by Category (Masculine, Neutral, Feminine) and Mean Ratings by Judges on Masculinity–Femininity

Category/item	Order of presentation	Mean rating
Masculine		
Oil a squeaky hinge on a metal box	2	4.30
Nail two boards together	4	4.60
Tighten a screw	5	4.50
Attach fishing tackle to a line	12	4.65
Neutral		
Play with a yo-yo	3	3.10
Sharpen a pencil	6	2.85
Peel an orange	7	2.95
Put a jigsaw puzzle together	9	3.00
Feminine		
Iron a cloth napkin	1	1.25
Set a table	8	1.50
Measure out a cup of flour	10	1.35
Sew a button to a piece of fabric	11	1.20

Note. Raters were 10 female and 10 male undergraduates.

Procedure

Subjects were tested in same-sex groups ranging in size from two to eight. Since Bem and Lenney (1976) reported stronger results for subjects tested by an opposite-sex experimenter, a pair of female undergraduate experimenters tested male subjects and a pair of male undergraduate experimenters tested female subjects.

Both experimenters were present at the beginning of the experimental session, one of them giving the initial instructions. Subjects were informed that they were participating in the initial phase of a study on impression formation designed to investigate whether observers' judgments about stimulus persons' personalities are influenced by the particular activity the latter are performing or how comfortable they are performing it. Subjects would therefore be asked to

rate a number of activities, several of which they would later carry out while being videotaped. Their data would be used to select activities for the later impression formation study. After a general description of the several types of activities had been given, subjects were informed that they would be given instructions about what to do or a statement to read while they were being videotaped. It was emphasized that there was no interest in how well they were doing the activity but that they were to try to become involved in what they were doing or saying, so that they would look believable.

The experimenter then told the subjects that they would be shown the whole list of tasks before the videotaping and asked for their reactions. The reason given for this procedure was to provide additional information about the tasks and to give the subjects some choice in what they would later be doing. The activities questionnaire was then administered. As each subject completed the activities questionnaire, the second experimenter took the subject into an adjoining room for videotaping.

Each subject was asked to perform a masculine and a feminine task from the list of everyday behaviors. One task was randomly selected from those the subject marked as most preferred and one was randomly selected from those the subject marked as least preferred. After the videotaping, each subject returned to the first room and completed the embarrassment questionnaire and the AWS.

Results

Everyday Behaviors

Comfort ratings. Summed comfort ratings were found for each subject on the masculine, feminine, and neutral tasks. Highly significant ($p < .001$) differences were found in each sex among the mean ratings for the three types of tasks, subjects rating sex-congruent tasks highest, neutral tasks intermediate, and cross-sex tasks lowest. Subjects' gender, then, was a strong determinant of reactions to the task. Within each type of task, however, correlations between the comfort ratings and PAQ M and F scores were all low positive, ranging in magnitude from .08 to .27. Four of these correlations were significant ($p < .05$): in males, the correlations between M and the masculine tasks, and in females, the correlations between M and F and the masculine tasks and between M and the feminine tasks.

This pattern of positive correlations provides preliminary support for our contention that within each type of task, those high in instrumentality and expressiveness would tend to give higher comfort ratings than others. A more direct confrontation between our hypothesis and Bem's is afforded by classifying subjects into categorical groups, based on their joint M and F scores. As illustrated in Figure 1, Bem's theory implies that on gender-incongruent tasks (masculine tasks for females, feminine tasks for males), individuals who are sex-typed in personality will show the lowest comfort ratings, whereas cross-typed individuals will presumably show the highest ratings. On gender-congruent tasks, however, all groups except the cross-typed are expected to show equally high ratings. Finally, no differences are predicted for the neutral tasks. In contrast, our expectations, drawn from self-esteem data, are that similar relationships occur in all three task categories in both sexes, androgynous subjects tending to have the highest means, followed by masculine and then feminine and undifferentiated individuals. Inspection of the means of the four categorical groups in both sexes on all three tasks showed good correspondence with the latter prediction, androgynous or masculine subjects having the highest ratings in all six comparisons and undifferentiated or feminine subjects the lowest.

The data from the masculine and feminine tasks were each analyzed by a 2 (Sex) × 4 (PAQ Category) analysis of covariance, using the neutral task ratings as the covariate. For both masculine and feminine tasks a highly significant ($p < .0001$) main effect was found for sex. For masculine tasks, the main effect of PAQ category was also significant ($p < .01$), but for feminine tasks, it was not ($p < .25$). Of particular importance, the Sex × Category interaction was nonsignificant ($F < 1$) in both analyses.

The pattern of the comfort data clearly does not support Bem's predictions of an interaction between sex, type of task, and PAQ category but corresponds quite closely to our expectations. Still further support for our hypotheses came from the finding that in both sexes, substantial positive correlations were found between the comfort measures on the three types of tasks (average $r = .67$).

The correlation between measures, in con-

junction with the analyses showing similar relationships with M and F in all task categories, led us to combine ratings on the three types of tasks to yield a single comfort score. Subsequent analyses, undertaken to explicate further the relationships among comfort ratings, PAQ scores, and sex role attitude (AWS) scores were based on the combined comfort measure. Presentation of the results of these analyses will be delayed until after the preference measure has been described.

Preference ratings. It will be recalled that each of the four tasks rated as most preferred was given a score of 3, those rated as least preferred a score of 1, and those unrated a score of 2. The sum of the ratings on the masculine, feminine, and neutral tasks was then obtained for each subject. Subjects exhibiting perfect sex-related preferences would thus have scores of 12 for congruent sex-typed tasks (masculine tasks for males; feminine tasks for females) and of 4 for noncongruent cross-typed tasks; parallel scores for those showing perfect cross-typed preferences would be 4 and 12. In initial analyses, means on the three types of tasks were obtained for males and females, the results indicating that in both sexes, the sex-congruent tasks were most preferred, followed by the neutral tasks, and then the cross-typed tasks. Within each sex, these differences were highly significant ($p < .001$).

A single score, called *preference,* was next obtained for each subject by subtracting the summed preference ratings for cross-typed tasks from the summed ratings for sex-congruent tasks. Possible scores thus ranged from 8 (12 − 4) for those with perfect sex-congruent preferences to −8 (4 − 12) for those with perfect cross-typed preferences. These difference (preference) scores were used as the dependent variable in subsequent analyses.

Relationships among variables. Correlations among the independent and dependent variables are shown in Table 2. As found in previous studies, M and F show low positive relationships in each sex. The relationships of M and F with the AWS also confirm previous findings, the signs of the correlations being theoretically coherent but the magnitudes low (and in this instance, nonsignificant).

Correlations for the combined comfort scores parallel previous reports for the ratings of each type of task: both M and F are positively related to the comfort measure in both sexes. As expected, M (instrumentality) is more strongly related to comfort ratings than F (expressiveness).

To examine the joint influence of trait and role attitude variables on the comfort mea-

sure, separate stepwise multiple regressions were performed for males and females.[1] The interaction term (M × F) was also included with the constraint recommended by Cohen (1978) that it be entered after the main effect terms. The regressions are summarized at the bottom of Table 3. Instrumentality (M) was most strongly related to comfort ratings, followed by expressiveness (F), the effects being larger in females than males. The AWS made no significant contribution. (Separate regressions on comfort ratings for the three types of tasks produced identical results.)

As another approach to the joint contribution of M and F, the mean comfort ratings have been plotted for the four PAQ groups of each sex in Figure 1. Analysis of variance of these data shows a significant main effect for sex, $F(1, 200) = 15.11$, $p < .001$, with females reporting greater comfort. The main effect for PAQ category is also significant, $F(3, 200) = 4.01$, $p < .01$, whereas the interaction F is less than 1. In both sexes, androgynous subjects gave the highest comfort ratings, followed by the masculine and then the undifferentiated and feminine subjects. The contrast of androgynous with all others is significant ($p < .001$), and androgynous and masculine versus undifferentiated and feminine approaches significance ($p < .06$).

Turning to the preference data, inspection of the correlations in Table 2 shows that in males the signs of the correlations were in theoretically coherent directions, stronger preferences for sex-congruent (masculine) tasks being positively associated with M scores and negatively associated with F scores. As we expected, the relationships were low, reaching significance only for M ($r = .28$; $p < .05$). Also as predicted, the relationship between AWS and preference scores was stronger than for M or F ($r = -.49$), with males who were traditional in sex role attitudes showing the greatest preference for sex-congruent tasks. Turning to females, even smaller correlations with M and F are found, neither significant. The AWS shows the largest correlation ($-.14$) with preference and is in the predicted direction, but even this relationship is nonsignificant.

Stepwise multiple regressions were also performed on the preference data and are shown at the top of Table 3. As we predicted, attitude scores provided the best prediction of sex-typed preference in males, followed by M. No significant effects were found in females.

Finally, the mean preference scores were examined for those in each of the four PAQ categorical groups. These means are plotted at the top right of Figure 1, while the results predicted by Bem are shown at the left. The most striking finding to be observed is the markedly greater preference of males than females for sex-typed tasks in all categorical groups except the undifferentiated. Analysis of these data, using a 2 (Sex) × 4 (PAQ Category) analysis of variance, revealed that the main effect for sex is highly significant, $F(1, 200) = 20.60$, $p < .0001$, accounting for 74% of the between-groups variance. The main effect for PAQ category is significant, $F(3, 200) = 2.18$, $p < .01$, as is the interaction between sex and PAQ category, $F(3, 200) = 4.47$, $p < .01$, reflecting a different ordering of means in the two sexes.

Simple analyses of variance by PAQ category within each sex were then undertaken. For females, the F was less than 1, but for males it was highly significant ($p < .001$). Contrasts of the male data indicated that the masculine subjects were significantly ($p < .01$) more sex-typed in their preferences than the androgynous and undifferentiated subjects but did *not* differ significantly from cross-typed, feminine subjects. Since Bem predicts no difference between androgynous and undifferentiated individuals, these groups were also compared. A difference of borderline significance, $t(45) = 1.7$, $p = .15$, was found, reflecting the higher preference of androgynous males for sex-congruent tasks.[2]

---

[1] If regressions are computed including sex as a predictor, highly significant overall Rs are obtained for each variable reflecting the strong sex effect. However, since the signs of correlations with criteria differ in the two sexes, the separate regressions give a clearer picture of relationships.

[2] Bem and Lenney classified their subjects as masculine, feminine, or androgynous using Bem's (1974) subtractive technique based on the concept of balance between masculine and feminine attributes. To max-

Table 3
Regressions of Masculinity, Femininity, and AWS on Sex-Typed Preference and on Comfort Ratings

Step	Variable	Entry F	p	Multiple R	R^2 change	Overall F	p
			Sex-typed preference				
Males							
1	AWS	28.9	.00	.49	—	28.9	.000
2	M	4.7	.03	.53	.04	17.4	.000
3	F	<1	*ns*	.53	.00	11.5	.000
4	M × F	9.8	.002	.60	.07	12.0	.000
Females							
1	AWS	2.1	.15	.13	—	2.1	.15
2	M	1.9	.16	.18	.02	2.0	.14
3	F	<1	*ns*	.19	.01	1.4	.26
4	M × F[a]	—	—	—	—	—	—
			Comfort				
Males

4	M × F	<1	*ns*	.33	.00	3.3	.010

Note. M = masculine. F = feminine. AWS = Attitudes Toward Women Scale.
[a] Data showed tolerance insufficient for inclusion.

An analysis of covariance was also performed on the male preference data, using AWS scores as the covariate. The term for AWS was highly significant ($F = 31.0$, $p < .001$), accounting for 65% of the explained variance and 23% of the total variance. The term for PAQ category was also significant ($F = 5.18$, $p < .01$), this variable accounting for 35% of the explained variance and 13% of the total variance.

Announcements. The data on announcements were collected primarily to determine whether the affective quality of sex-linked activities interacted with the PAQ measures in determining preference and comfort ratings. Although significant main effects were found for the positive and negative tasks within the masculine, feminine, and neutral categories in both preference and comfort ratings, no interactions involving category and the PAQ measures occurred. Accordingly, results for positive and negative tasks were combined, and analyses paralleling those performed with the everyday task data were conducted. Sex differences related to type of task were highly significant. The contribution of the PAQ scales to the criterion measures was somewhat weaker than was found with the everyday tasks data, but the overall pattern of the results for the comfort and preference ratings was similar. For this reason, they will not be discussed further.

imize comparability of analyses, subjects were also classified into three groups by applying Bem's procedure to PAQ M and F scores. The preference and comfort scores were then analyzed in 2 (Sex) × 3 (Masculine, Feminine, Androgynous) analyses of variance. The pattern of means for preference paralleled Bem and Lenney's results, whereas those for comfort did not. In both analyses of variance, however, only the sex main effect was significant.

Discussion

Mounting evidence suggests that the PAQ and the BSRI have both construct and predictive validity as measures of instrumental (masculine) and expressive (feminine) attributes. The question to which the present study is fundamentally addressed is whether the masculine and feminine attributes tapped by these psychometric instruments are both strongly and directly related to other masculine and feminine behaviors and attributes, as implied by Bem's theory, or whether these personality attributes tend to be only weakly and indirectly related to sex-related phenomena that do not quite immediately engage instrumental and expressive capacities, as suggested by the present investigators.

Overall, the data from the present study support the latter point of view. Analyses of the ratings of anticipated comfort in task performance showed, as we predicted, weak but positive correlations with M and F in *both* sexes on all three types of tasks, masculine, feminine, and neutral. Assessment of the joint contribution of M and F scores, conducted by assigning subjects to categorical group, indicated that androgynous individuals of both sexes expressed the greatest comfort (on all tasks combined), followed by masculine, undifferentiated, and feminine subjects. Except for the inversion of the undifferentiated and feminine groups (who were, in any event, very similar), this ordering corresponds to that consistently found with measures of self-esteem (e.g., Spence & Helmreich, 1978), bolstering our contention that the relationship between the trait factors and comfort ratings may have been mediated through self-esteem. On the other hand, Bem's theory, which predicts an interaction between PAQ category, sex of subject, and type of task, received no support.

The forced-choice preference ratings were more likely than the comfort ratings to compel the appearance of any association that exists between instrumental and expressive traits and preferences for the kinds of mundane, sex-related tasks we investigated. The results from females were essentially negative, the PAQ (and the AWS) variables being nonsignificantly related to preference for gender-congruent tasks. Positive results, however, were found in males, who as a group, it is interesting to note, showed strikingly higher preference ratings than women. Masculine men exhibited significantly higher preference ratings than did androgynous and undifferentiated men but, curiously enough, nonsignificantly higher ratings than did cross-typed feminine men. One other aspect of these findings from males should also be mentioned. As we predicted, our measure of general sex role attitudes (AWS) was more strongly related to the preference measure than were PAQ scores and, in analyses by PAQ category, accounted for almost twice as much of the variance as the latter. (Had a general measure of *personal* sex role choices been included, even stronger relationships with preference ratings might have been obtained, not only in males but in females.)

The preference data from the male subjects replicate the findings of Bem and Lenney that sex-typed subjects (in this instance, masculine men) show the greatest preference for gender-congruent tasks on a forced-choice measure. This finding supports Bem's theory, but the relative performances of the remaining groups did not provide confirmation of other predictions derived from her theory. Finally, the PAQ variable, even in males, contributed only weakly to the preference ratings. When these data are viewed in the context of all the available evidence, they appear to us to be more supportive of our contention that the trait dimensions measured by the scales are not only *conceptually* distinguishable from various classes of sex role behaviors and attitudes but are often only *minimally* associated with these other sex-related phenomena, if at all.

Finally, even the male preference data do not support the broad hypothesis that androgynous individuals, high in instrumental and expressive qualities, are more behaviorally flexible in their *sex role behaviors* than are those in other categorical groups. The evidence to date suggests that the androgynous are more flexible than others in the limited sense of manifesting a higher degree of both instrumentality and expressiveness in their behavior but that the extension of the

flexibility notion to include sex-related behavior in general is unwarranted.

A question that remains to be answered is why the present results were seemingly weaker than those reported by Bem and Lenney (1976). One explanation may be that the population effects were weak but a greater number of significant findings occurred in that study because subjects were selected from extremes of the distribution of combined M and F scores. The possibility cannot be discounted that procedural discrepancies may have brought about differences in the magnitude of effects in the two studies. However, it should be acknowledged that if method factors are responsible, the generalized *sex role* rigidity purportedly exhibited by individuals who are sex-typed in personality characteristics is an extremely fragile phenomenon rather than the robust one suggested by Bem's theory.

Finally, differences in the BSRI and the PAQ may be cited. The PAQ M and F scales, as we have demonstrated, form unidimensional clusters of socially desirable instrumental and expressive traits. Many of the BSRI M and F scale items can be similarly characterized. Others cannot, however, and the inventory is factorially more complex than the PAQ. These "extraneous" elements may bring about a stronger relationship with sex role behaviors. A specific hypothesis can be derived from a recent analysis of the psychometric properties of the BSRI by Pedhazur and Tetenbaum (1979). These investigators point out that the inclusion of the terms "masculine" and "feminine" on the M and F scales, respectively, greatly influences the discriminant ability of the instrument and also its factor structure. For example, in a discriminant function analysis between male and female respondents, 96.7% of the sample were correctly classified as to gender by the full function (all 40 items), but 93.5% were correctly classified by using the function based on the adjectives *masculine* and *feminine* alone. Factor analyses in each sex yielded four interpretable factors, "masculine" and "feminine" forming a separate, bipolar factor, with "feminine" having a positive loading and "masculine" a negative one. Given the demonstrated import of these two adjectives, it may be that their inclusion to some degree evokes schemata (Markus, 1977) of appropriate masculine and feminine roles and that these schemata may influence endorsement of the trait adjectives that follow their appearance. Admittedly, this is putting a heavy explanatory burden on two items. More generally, interpretation of data obtained with the BSRI will be facilitated if there is better understanding of the influence that the presence of the subset of items that do not tap socially desirable instrumental and expressive traits has, both on responses to the items that do describe such traits and on the relationships of each subset of items to other behavioral and self-report measures.[3]

[3] Bem (1979) has recently developed a Short BSRI dropping, notably, the items *masculine* and *feminine* as well as those with low social desirability. It seems reasonable to hypothesize that results from subjects classified by either the median split or difference method on the Short BSRI would be closer to those obtained in the present study.

Nonverbal Trait Inference

Sampo V. Paunonen and Douglas N. Jackson
The University of Western Ontario, London, Canada

The purpose of this study was to evaluate empirically the view that personality trait inferences merely reflect consistency in linguistic associations among verbal trait descriptors and have little correspondence with the actual organization of behavior. Trait inferences were obtained in both verbal and nonverbal rating contexts to evaluate their relative reliability, accuracy, and structure. Eighty male and 80 female undergraduates were supplied with either a verbal or nonverbal (cartoonlike) description of one of two target persons and were required to estimate the probability that the target would endorse both verbal and nonverbal self-descriptive personality items. Results indicated very similar reliabilities, accuracies, and structures for the different conditions. The results are interpreted as not supporting the view that explicit semantic cues are necessary in accounting for observed consistencies in ratings of personality. Alternative hypotheses of desirability and the mediation of nonverbal inferences by some putative covert verbal process are evaluated and are found not to be supported by the data.

One of the dogmas in some current theories about personality and the perception of personality is that there are few consistencies, at least of the sort that can be attributed to broad behavioral dimensions or dispositions. Evidence from a variety of sources regarding consistencies in behavior has not been lacking, but its interpretation as being due to broad personality dispositions has been disputed. For example, ratings made about the personality of others in a variety of situations have consistently yielded a stable structure (Wiggins, 1973, pp. 328–349). But the fact that such studies have typically employed semantic trait names has raised doubts regarding the extent to which these consistencies are attributable to underlying behavioral consistencies in the person being rated. D'Andrade (1965) obtained a similar factor structure for 20 traits judged for "similarity of meaning" that had been identified previously by Norman (1963) from data based on ratings of peers. From these data D'Andrade (1965) attempted to draw a general conclusion: "Some of the classifications used by psychologists can be derived solely from similarities in the meanings of words without considering any sample of actual behavior" (p. 215). Similarly, Mulaik (1964) suggested that parallel findings derived from people ratings and word ratings "serve to focus attention upon the role of conventional linguistic usage in determining the correlations between trait rating scales" (p. 507).

The findings of D'Andrade and of Mulaik, advancing the hypothesis that observed consistencies in rating others might be due to linguistic conventions, have been highlighted by others as evidence against the existence of traits or other broadly based regularities in behavior. For example, Mischel (1968) indicates that "so-called traits at least in part exist as components of the verbal terms used to describe the external world; they do not

The authors especially thank Deirdre Flavin for drawing nonverbal stimulus materials. This study was supported by the Social Sciences and Humanities Research Council of Canada Research Grant 410-77-0320-R1, Douglas N. Jackson, Principal Investigator, and Fellowship 453-784712 to Sampo V. Paunonen.

necessarily mirror the external world itself (D'Andrade, 1965)" (p. 46). As time has passed, earlier tentative statements of this "semantic similarity" hypothesis have tended to be treated as established law. Schneider (1973), for example, states, "The claim is made and indeed rarely questioned that various kinds of linguistic structures produce the implicit personality theory" (p. 302). Bandura (1969), D'Andrade (1974), Mirels (1976), Mischel (1976), and Shweder (1975), among others, have argued forcefully for the primacy of "linguistic characteristics," "concept meanings," "preexisting conceptual schemes," or some similar term in influencing the perception of generalized response dispositions. But rarely are these terms clearly and explicitly defined.

The concept of "similarity of meaning," which is central to the issue, since judgments of the similarity of word meanings have been used to assess the "cognitive structure" of raters, is somewhat obscure in that it has been the subject of a variety of interpretations, not all of which have been made explicit by researchers and not all of which are mutually consistent (D'Andrade, 1974, pp. 177–180). D'Andrade (1974) recognizes this as a "critical problem" and states that, in his treatise, "measures of conceptual similarity have been phrased primarily in terms of semantic similarity" (p. 177). Moreover, he discusses several varieties of semantic similarity and concludes, "it is somewhat ironic that the problem of not knowing what is happening when people are used as measuring instruments, raised at the beginning of this chapter and given as the reason why certain procedures in the social sciences produce invalid results, returns to plague a later formulation about exactly how these invalid results come about" (p. 180). In view of the confusion surrounding the nature of the process purportedly invalidating ratings of personality, it is necessary to state clearly which version of the semantic similarity hypothesis is under investigation in the present study.

Most studies involving ratings of the personalities of others have used verbal trait labels as reference points for rating scales. It has been conjectured that the "similarity in meaning" of these verbal trait descriptors rather than "real world" similarity may account for the observed consistencies in these rating studies. To our knowledge, this hypothesis has not been sufficiently delineated to allow for predictions of potential effects due to varying degrees of verbal and nonverbal target information, target-relevant versus target-irrelevant information, type of rating scale used, or other parameters conceivably biasing trait inferences. D'Andrade (1965), however, underscores the fact that the classification of traits by rating scales has been *confounded* with the use of verbal trait descriptors. Consequently, he questions the significance of trait attribution research, since it is difficult to ascertain whether "studies that have reported in various forms correlations between two or more linguistic labels have been reporting about relations between real world events, or about how similar in meaning the labels are, or some complex interaction of meanings and external events" (p. 228). It is our intention in this study to unconfound the use of verbal materials in designating traits from the trait descriptions by employing nonverbal as well as verbal stimulus and response materials in a trait inference paradigm.

If the observed consistencies in the ratings of personality are simply a product of the words used by experimenters, it is possible that these ratings, as merely a reflection of the perceivers' "cognitive structures," will not correspond to the actual organization of behavior as measured more objectively. An alternative position is the *isomorphism* hypothesis, that relations between semantic cues are highly associated with the actual probable co-occurrence of the behaviors reflected by the verbal cues. Certain authors (D'Andrade, 1974; Shweder, 1975) entertain this possibility, but favor the interpretation that linguistic associations somehow determine the observed, invariant structures and that these structures have little correspondence with the actual organization of behavior. Of course, if the isomorphism hypothesis were confirmed, if semantic meaning were shown to mirror behavioral consistencies validly, such a finding would only serve to reinforce confidence in

the validity of observed behavioral consistencies or traits. Results apparently at variance with the isomorphism hypothesis (D'Andrade, 1974; Shweder, 1975) have been challenged by Block, Weiss, and Thorne (1979).

The issue is an important one theoretically and one about which there is conflicting evidence. Lay and Jackson (1969), for example, found that the structure observed for multidimensional scaling of trait names was similar to that obtained when actual Personality Research Form (PRF) (Jackson, 1974) items were used, which referred to more concrete behavior than that implied by abstract trait names. Furthermore, these structures were quite similar to the factor structure derived from factor analytic findings based on responses to the entire PRF by different subjects. Chan and Jackson (1979) have obtained similar results in the domain of psychopathology.

Recently, Mirels (1976) reported a lack of any statistically significant relationship between judgments of conditional probability of responses to pairs of the Lay and Jackson PRF items and observed conditional probabilities of respondents, claiming that such presumed relationships were "illusory." But Jackson, Chan, and Stricker (1979) reanalyzed Mirels' data and reported new data indicating that when the more appropriate product–moment correlation is used as an index of behavioral co-occurrence rather than conditional probability as used by Mirels, the association between judged and actual co-occurrence of behavior is highly statistically significant and substantial. The evidence seems to suggest that "subjects make judgments of item coendorsement on some basis other than conditional probability" (Jackson et al., 1979, p. 9). Reed and Jackson (Note 1) report a number of studies indicating that when target persons are judged on the basis of broad descriptive paragraphs, the behavior of actual persons like the targets can be predicted with a high degree of reliability and accuracy. When base rate and desirability were also taken into account, predictive validities reached as high as .95.

Further evidence of the relevance of trait ratings comes from a study by Norman and Goldberg (1966). These authors demonstrated greater interrater reliability and criterion validity for peer ratings made on close as opposed to distant acquaintances. Kusyszyn (1968) and Jackson, Neill, and Bevan (1973) also reported similar findings. This observation suggests that raters' perceptions are veridical when they have relevant information upon which to base their ratings. In addition, since Norman and Goldberg analyzed ratings made on the same variables used by D'Andrade (1965), their results lend credence to the notion of an isomorphism between meaning factors and person factors. From the present vantage point, however, all of these studies confounded the use of verbal rating scales and the question of veridicality.

The question arises: Is the frequently observed organization of behavior in ratings of others solely a function of explicit verbal informational cues and verbal rating scales, or might this same structure arise in the absence of such semantic cues? In this study we propose the use of a method not depending upon explicit linguistic elements in the forming or reporting of inferences about the behavior of others. Judges will be asked to make inferences about the behavior of a target person who will be characterized with pictorial representations of some concrete behaviors in which linguistic elements are lacking. Similar pictorial information, again based on the figural representaton of concrete behaviors in a diversity of situations, will be used for obtaining ratings of the probability that a particular target individual will engage in particular behaviors. Also, we propose to include more traditional verbal personality statements or items for comparison purposes, both for providing information about a target person and for obtaining judgments regarding the behavior of particular target individuals. The proposed design separates verbal and nonverbal cues, both in terms of the information used to form an impression of the individual and in terms of the vehicle used in communicating that impression. The study is thus designed to investigate (a) the degree to which consistencies in rated behavior depend upon explicit linguistic or semantic characteristics,

(b) the degree to which verbal and nonverbal information yields inferences about behavior that conform to personality types observed empirically, and (c) the structure of perceptions of personality elicited by verbal and nonverbal materials. We hypothesize that there will be a high degree of consensus among judges regardless of whether verbal or figural cue information or rating scales are used and that, on the whole, judges' characterizations of the behavior of target persons will conform closely to the structuring of the behavior as observed empirically. We are not hypothesizing that individuals necessarily avoid all use of implicit semantic reasoning processes in drawing inferences about personality, but rather that explicit verbal cues, that is, those supplied by the experimenter in transmitting and receiving information, are not a necessary prerequisite for the identification of stable predictions regarding the behavior of others.

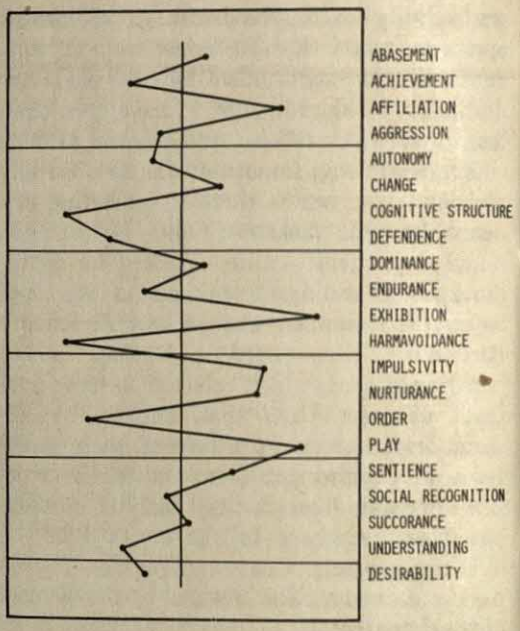

Figure 1. Criterion Profile 1, based on 796 Personality Research Form E male respondents (basis for Ed Nolan target).

Method

Experimental Design

Psychology undergraduates were used in this study as raters who were instructed to make estimates concerning the probability that a target would endorse certain self-descriptive personality items. Each rater was presented with a limited amount of information describing one of two possible targets depicted as having distinct behavioral characteristics. Each of the target characterizations consisted either of a verbal personality sketch or of a set of nonverbal cartoonlike drawings showing a target individual engaging in certain behaviors. Predictions of the likelihood of behavior in particular situations were of one of two types: (a) ratings of the probability that the target individual would endorse each item of a particular set of verbal personality items and (b) a prediction that the target person would engage in the particular behavior depicted by a central figure in each of a number of nonverbal drawings. Predictions of the likelihood of behavior were completed in one of two orders: (a) predictions based on nonverbal drawings first, followed by predictions of responses to verbal personality items, designated Order 1, and (b) predictions based on verbal personality items first, followed by predictions of the behavior depicted by the nonverbal drawings, designated Order 2.

Construction of the Target Descriptions

Subjects were instructed to make behavioral predictions for one of two target characters, who were described either verbally or nonverbally. The attributes of the targets were based on distinct personality types derived empirically from a multivariate clustering procedure (Jackson & Williams, 1975; Skinner, 1977; Skinner, Jackson, & Hoffmann, 1974). Given a matrix of profiles representing the scores of a number of persons on a number of personality scales, this procedure identifies dimensions of persons based on profile shape using an Eckart–Young (1936) decomposition of the data matrix. Persons having similar profiles occupy similar positions in the orthogonal n-dimensional space. Each cluster of individuals is represented by a set of standardized component scores typifying the profile of persons receiving high scores on the dimension.

Figures 1 and 2 show two of five bipolar "modal" profiles extracted from a sample of 796 PRF respondents. These two orthogonal configurations were used as the basis for forming the target descriptions for the present study and were used as the criterion profiles in the assessment of judgmental accuracy. Because the scale means are removed as a first step in the derivation of the modal profiles from the respondent by scale matrix, predictions of these standardized scores cannot be based on stereotype accuracy, as defined by Cronbach (1955; Wiggins, 1973). Judgments seeking to predict these profiles of scores cannot be accurate as a function of the raters' "knowledge of the relative frequency or popularity of the possible responses" (Cronbach, 1955, p. 179) since the "average item self-description summed over all others" (Wiggins, 1973, p.

127) represents a null vector and as such contributes no variance to the individual target profiles. Hence, judgments based on "accuracy in predicting the generalized other" (Cronbach, 1955, p. 179) would, in general, not contribute valid variance to the predictions of these criterion profiles.

An alternative procedure for identifying criterion personality trait profiles associated with a certain type would have been simply to obtain the personality scores of one or more persons highly associated with one of the typal dimensions (Reed & Jackson, Note 1). Although such a procedure has the advantage of simplicity and concreteness, and indeed would yield very similar results, scores so obtained would not be completely free of the stereotype component. But in either case we are dealing with a set of scores derived from the responses of real people, scores that have been shown to possess a degree of convergent and discriminant validity (Jackson, 1974).

Four of the most characteristic traits of Criterion Profile 1 (Figure 1) were used to describe the first target (Ed Nolan). This target was depicted as high on PRF scales for affiliation, exhibition, nurturance, and play. The second target (John Newman) was based on Criterion Profile 2 (Figure 2), denoted by the attributes of aggression, autonomy, dominance, and thrill-seeking (low harmavoidance).

Verbal target descriptions consisted of a name and five sentences written in third-person narrative form and presented as a personality sketch. For example, Ed Nolan was described to raters as follows:

> Ed Nolan is a sociable person who enjoys being with friends and people in general; in fact, he makes an effort to win friendships and maintain close acquaintances. Ed spends a lot of time participating in games, sports, and various social activities and often likes to play practical jokes on his fellow workers. His friends describe him as being very entertaining and delighting in behaviors that attract the attention of an audience. Ed also readily performs favors for others and gives sympathy and comfort to those in need. When people have a problem they often go to Ed for encouragement and consolation.

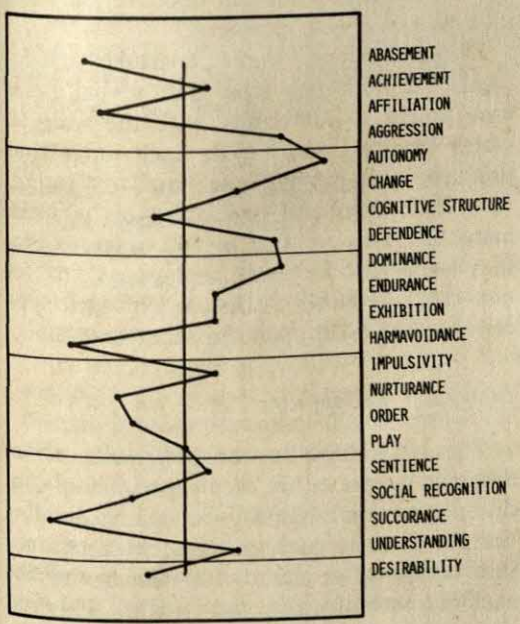

Figure 2. Criterion Profile 2, based on 796 Personality Research Form E male respondents (basis for John Newman target).

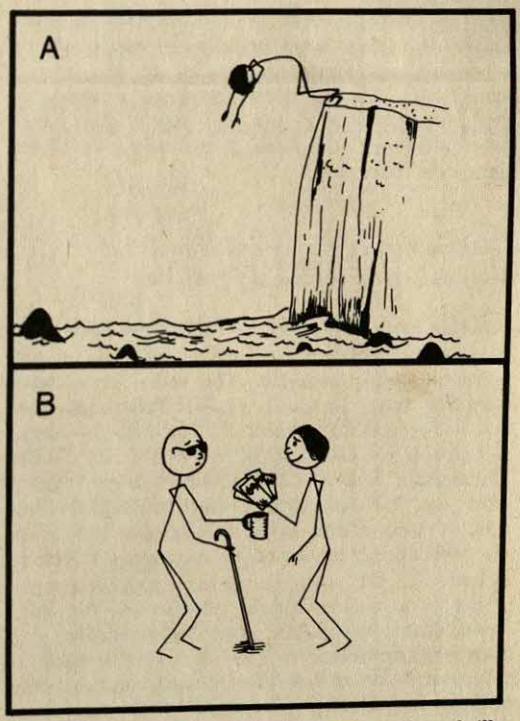

Figure 3. Sample nonverbal items depicting thrill-seeking behavior (A) and nurturant behavior (B).

The items for the nonverbal target descriptions were prepared by commissioning an artist to illustrate a series of scenarios supplied by the authors. Ideas for these scenarios originated from a careful perusal of PRF scale definitions and items. Each illustration consisted of a stick drawing of a central figure performing a behavior in a specific context. An attempt was made to convey pictorially a behavioral manifestation that would be characteristic of a person defining an extreme position on the substantive dimension of interest. For example, the upper panel of Figure 3 shows a nonverbal stimulus designed to reflect high thrill-seeking (low harmavoidance) in the central character, while the lower panel reflects high nurturance. Four items were conceptualized and illustrated for each of the four behavioral dimensions typifying each target, with an emphasis on nonredundancy of item content. In

composing the nonverbal trait descriptions, an attempt was made to imply behavioral consistency and to convey an impression parallel to the verbal counterparts. The 16 items describing a character were randomly ordered in a four-page booklet bearing a picture and the name of the central or target figure on a cover page.

Construction of Verbal and Nonverbal Materials for Behavioral Prediction

Judges were instructed to make behavioral predictions separately on the basis of both verbal and nonverbal rating materials. The verbal items were extracted from Jackson's (1974) Personality Research Form (PRF), Form E. The first five items for each of 17 content scales and two validity scales (infrequency and social desirability) were selected from the PRF test booklet. Each scale had either two or three items keyed in one direction, with the remainder being keyed in the reverse direction.

Items for the nonverbal rating scales were composed in a manner similar to that of the nonverbal target description scenarios. A total of five rationally constructed nonverbal items for each of 17 content scales was created with unidirectional keying. In addition, a five-item validity scale was compiled, reflecting undesirable behaviors but heterogeneous with regard to content or the possible personality scale on which they might be keyed. Three of the content scales of the PRF were not depicted because they represent particularly difficult constructs for nonverbal definition—cognitive structure, change, and defendence. These constructs were also absent in the verbal rating scales.

Each of the 90 nonverbal items was rated for desirability by 12 psychology graduate students using a 9-point rating scale, ranging from *extremely undesirable* to *extremely desirable*.

Subjects and Procedure

Subjects consisted of 80 male and 80 female introductory psychology students completing a course requirement. Run in groups of about 20, each subject was assigned to one of the cells in the design by randomly allocating different booklets to subjects as they appeared. This resulted in 10 males and 10 females in each rating situation.

Each participant was given a folder containing (a) some preliminary information common to all; (b) instructions specific to the rating situation; (c) a target description corresponding to one cell of the design; and (d) the verbal and nonverbal rating scales (order predetermined). The common preliminary information was read aloud by the experimenter while the subjects simultaneously read their text. The specific instructions were read silently by each participant; these instructions were equivalent across raters in form and wording except for necessary modifications such as interchanging the words *verbal description* and *nonverbal description*.

The directions for completing the verbal rating scales instructed the subjects to make a judgment, using a 9-point scale, on the probability that the described target would endorse each of the verbal statements. Instructions for the nonverbal rating scales stated that judges were to estimate the likelihood that the described target would engage in the behaviors depicted by the central figure in each item. Judgments were again recorded on 9-point scales.

Results

Overview of Analyses

The analyses may be divided into three stages corresponding to the three major questions addressed. First, interjudge reliabilities were computed to evaluate the degree to which raters share a consensus regarding their interpretation of nonverbal and verbal items or behavioral exemplars. Second, an assessment was undertaken to appraise the degree to which judgments based upon behavioral exemplars are valid in the sense that they show a pattern of inferences consistent with the structure of behaviors observed empirically. Third, the structures of inferences based upon nonverbal and upon verbal stimulus materials were compared.

Before analyses were undertaken, judgments for both nonverbal and verbal items were scored in conformity with the scale on which the item was keyed. Each judge thus produced two profiles, one based on ratings of verbal items and one based on pictorial materials. This resulted in 160 separate profiles for verbal judgment scales and 160 for nonverbal judgment scales, one of each type for each of the 20 judges in each condition.

Interjudge Reliabilities

The generalizability of judgments across different judges within each experimental condition was appraised by randomly dividing the 20 raters in each of the eight conditions into two equal groups of 10, each having the same number of males and females. This was done separately for nonverbally and verbally based profiles. The 10 profiles were then averaged separately for each of the two randomly

divided groups. The two mean profiles, consisting of 18 scales each (17 content scales and social desirability), were correlated. Table 1 reports interjudge reliabilities corrected by the Spearman–Brown formula to yield an estimate of within-cell group reliability (Gulliksen, 1950, p. 66). These values range from .93 to .99 and reveal a consistently high degree of consensus across treatment groups, targets, verbal and nonverbal descriptions, and verbal and nonverbal judgmental items. Of particular interest is the absence of a significant difference in group reliabilities between verbal and nonverbal rating scales. Average values of .96 for nonverbal and .97 for verbal conditions indicate that high levels of judgmental consistencies are not predicated solely on the presence of an explicit semantic structure in rating scales.

The Spearman–Brown formula was also used to derive estimates of single-subject reliabilities for each of the conditions. These range from .40 to .83, with a mean of .61 over all 16 conditions. More properly, these coefficients reflect the generalizabilities of judgmental sensitivities over judges expressed in terms of single judges. Were we seeking to develop a reliable test of judgmental sensitivity for single judges over targets, many more targets than one per judge, used here, would be appropriate, because targets are analogous to items on a test.

Table 1
Interjudge Reliabilities for Eight Experimental Conditions for Nonverbal and Verbal Ratings

Target description	Rating scale: Nonverbal	Rating scale: Verbal
Ed Nolan		
Order 1		
Nonverbal	.96	.98
Verbal	.93	.94
Order 2		
Nonverbal	.98	.96
Verbal	.98	.97
John Newman		
Order 1		
Nonverbal	.94	.97
Verbal	.96	.97
Order 2		
Nonverbal	.97	.99
Verbal	.98	.98

Note. Order 1 = predictions based on nonverbal drawings first, followed by predictions of responses to verbal personality items. Order 2 = predictions based on verbal personality items first, followed by predictions of the behavior depicted by the nonverbal drawings.

Evaluation of Judgments in Terms of Modal Types

In the present study, experimentally derived profiles based on the raters' judgments were expected to emulate empirically obtained criterion personality profiles (Reed & Jackson, Note 1). A close correspondence between the two is an indication of the accuracy of the inferential judgments observed in the present study. Such evidence would support the interpretation that the inferred relationships between personality characteristics accurately reflect these relationships as revealed in the covariation of responses to structured personality items.

Individual accuracies or *sensitivities* (Jackson, 1972; Reed & Jackson, 1975), reflecting the degree to which a judge manifested judgments congruent with observed behavioral consistencies, were computed by simply correlating both of his/her judgmental profiles of 17 content scales with the relevant criterion profile. Group sensitivities were obtained by first averaging the 20 individual profiles in a treatment condition and then correlating this group mean profile with the relevant criterion profile. These sensitivity indices were computed separately for both verbal and nonverbal rating scales. This computational technique (i.e., the product–moment correlation between two profiles) measures the degree of similarity between each judge's rating of the target profile shape and the profile shape as identified empirically in groups of respondents.

Individual sensitivities ranged from −.40 to .93. Sensitivities falling below the .30 level (of which there were only about 13%), like high PRF infrequency scores, can be attributed not only to a subject's lack of awareness of trait relationships, but possibly to some

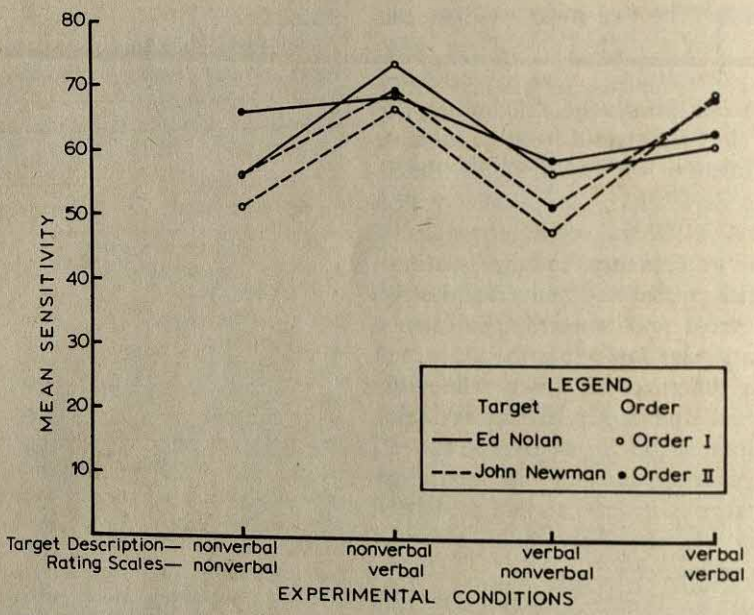

Figure 4. Mean sensitivities for nonverbally and verbally based judgments of behavior, by condition.

combination of lack of motivation, misconstrued instructions, random responding, or deliberate noncompliance. Figure 4 shows the means for the individual sensitivities for each experimental group. The most salient feature of Figure 4 is the substantial level of average sensitivity to trait covariation across targets and experimental verbal and nonverbal conditions. One notes also in Figure 4 a modest decrease in mean sensitivities for nonverbal ratings as opposed to verbal ratings, in each condition. However, verbal and nonverbal informational cues appear to result in similar levels of group sensitivity. To test these effects for significance and to examine any other effects on sensitivity due to the factorial manipulations, a four-way fixed-effects analysis of variance was run using the nonverbal and verbal rating scales as two levels of the fourth factor. Subjects were nested in the other three factors (description type, target person, order of dependent variables), and the data used as the dependent variable was the individual sensitivity index (this is referred to by Kirk, 1968, Section 8.13, as a split-plot factorial 222.2 design). This analysis revealed a significant main effect of rating scale type; sensitivities were attenuated when judgments were made on the nonverbal scales as opposed to the verbal items, $F(1, 152) = 51.58$, $p < .001$. Only one other effect was observed, and that was a Rating Scale × Target interaction, $F(1, 152) = 7.47$, $p < .01$; the drop in sensitivities as one examined the nonverbal judgmental profiles compared to the verbal profiles was more noticeable with the target John Newman (based on Criterion Profile 2). It should be emphasized that although they were significant, these effects account for a relatively small proportion of the variance. It should also be emphasized that the type of information used to form an impression of the person (verbal or nonverbal) and the order factor had no effects on rater accuracy. A separate analysis investigating whether or not gender of rater affected ratings also revealed no significant differences.

Table 2 shows the sensitivity of the group as a whole for both the verbal and nonverval personality rating scales for each of eight conditions. The accuracy of the group consensus in estimating the personality characteristics of the targets ranges from values of .58 to .95. This accuracy seems to occur regardless of the target being rated, the na-

ture of the target description, the order of dependent measures, or the nature of these rating scales.

The mean correlation of the group mean profiles based on the Ed Nolan target with the John Newman criterion profile is −.22. When the group mean profiles based on John Newman are correlated with the Ed Nolan criterion profile, the average correlation is .18.

Evaluating the Role of Desirability

The argument that the group sensitivities were simply based on the connotative social desirability components common to target descriptions and rating scale items was put to test by partialing this portion of the variance out of the ratings and recomputing the group sensitivities using standard partial regression techniques to control statistically the effects of desirability in both the predictor and the criterion.

Because the predictor profiles were based on either verbal or nonverbal items, two different desirability vectors were used for this analysis; the social desirability values of the scales as given in the PRF manual (Jackson, 1974, p. 12) were partialed from the verbally based profiles and the criterion profiles. The corresponding values for the nonverbal scales were obtained from the social desirability ratings of the nonverbal items. This vector was partialed from the judgmental profiles based on those items and the criterion profiles. The correlation between the two social desirability vectors is .82. Group sensitivities corrected for desirability are presented as parenthesized values in Table 2. A comparison with the uncorrected values reveals that there is little if any evidence that any of these values decline as a function of eliminating desirability. In fact, there is some evidence that desirability is acting as a suppressor variable (Conger & Jackson, 1972); when its effects are removed, accuracy in predicting the criterion profile is slightly increased.

After the effects of desirability had been removed from the correlations between the predictor and criterion profiles, estimated population base rates were partialed from these correlations. The vector of PRF Form E mean scale scores for males (Jackson, 1974, p. 42) was partialed from the correlations with the verbal rating scales. The mean change in group sensitivity is .01. A vector of mean scale scores derived from the self-reports of 128 male respondents to a set of 202 nonverbal items, of which the nonverbal rating scale items used in this study formed a subset, was partialed from the correlations with the nonverbal rating scales. A mean change in group sensitivity of .01 is also observed in this analysis, indicating that the prediction of population endorsement frequencies was not a large component of the subjects' judgments of either target.

Table 2
Correlations Between Group Mean Profiles and Criterion Profiles, by Condition

Target description	Rating scale: Nonverbal	Rating scale: Verbal
Ed Nolan		
Order 1		
Nonverbal	.73 (.80)	.93 (.94)
Verbal	.73 (.79)	.84 (.85)
Order 2		
Nonverbal	.85 (.91)	.95 (.95)
Verbal	.76 (.77)	.83 (.83)
John Newman		
Order 1		
Nonverbal	.77 (.78)	.84 (.84)
Verbal	.58 (.61)	.81 (.81)
Order 2		
Nonverbal	.75 (.77)	.84 (.84)
Verbal	.63 (.67)	.83 (.82)

Note. Correlations with social desirability partialed out are in parenthesis.

Evaluating the Structure of Verbal and Nonverbal Cues

A multivariate analysis of variance (MANOVA) was used to evaluate the effect of the factorial manipulations on the 18 component profiles of trait ratings. The analysis (a multivariate split-plot factorial with rating scale type as the within-block treatment and description type and order of ratings as the between-block treatments) was run separately for the ratings of the target John Newman and the target Ed Nolan. The mean profiles

for the various conditions are presented in Table 3.

The MANOVA revealed the following effects for the ratings of John Newman (using Wilks' lambda criterion). Description type and rating scale type were both significant beyond the .001 level, approximate $F(18, 59)$ was 3.25 and 29.9, respectively, and there was a significant Description Type × Rating Scale interaction, $F(18, 59) = 2.7$, $p < .003$. The same effects were replicated with the Ed Nolan target, $F(18, 59) = 2.7$, $p < .003$; $F(18, 59) = 19.0$, $p < .001$; $F(18, 59) = 4.8$, $p < .001$, respectively, in addition to a significant order effect, $F(18, 59) = 1.9$, $p < .04$.

Despite the above differences among the mean vectors, an examination of the intercorrelations of these mean profiles of Table 3 shows a substantial degree of consensus for all experimental groups judging the same target. The within-target values all exceed .70, with the mean for the target John Newman being .87 and that for the Ed Nolan target being .86. The mean heterotarget correlation, however, was only −.02.

A principal components factor analysis was undertaken to seek to identify the relative contributions of the descriptive attributes of the targets and the experimental manipulations on the judgments. Components were extracted from the intercorrelation matrix of group mean profiles for each target. In this analysis, the experimental conditions were treated as variables and the trait dimensions as replications. For both targets, the largest components in Table 4 show a pattern of high positive loadings, accounting for more than 88% of the total variance. Since the primary common element running through all eight sets of ratings was the common target, this factor may be interpreted as reflecting a consistent conception of the attributes of the target person, cutting across the different combinations of verbal and nonverbal sets of cues and response formats. The second factor, accounting for somewhat less than 9% of the variance for each target, is a bipolar dimension, clearly separating ratings made on the nonverbal personality rating scales from ratings made on the parallel verbal form. The third factor, although very small, consistently separates ratings based on verbal and nonverbal target descriptions.

Discussion

The authors recognize certain limitations of the present study. Only one type each of verbal and nonverbal material was used, making it difficult to substantiate claims of generalizability to other rating situations. Any differences in the judgments of verbal and nonverbal rating scale items may have been the consequence of slightly different instructional sets for completing these ratings. Also, rating validities might have been different had a more objective criterion measure of

actual target behavior been available rather than that based on self-report data. In spite of these limitations, the results clearly demonstrated that (a) judges showed extremely high degrees of agreement when inferring the behavior of a target from limited information; (b) although profile differences were found across verbal and nonverbal conditions, the profile similarities were more interesting; (c) highly similar factor structures were attained regarding the perceived patterning of target traits across verbal and nonverbal informational and rating conditions; (d) the ratings of two targets were approximately orthogonal, corresponding to the orthogonal patterning of target characteristics as measured empirically; (e) although there was somewhat less accuracy regarding the prediction of behavior using pictorial items as compared with verbal items, both sets of rating formats yielded substantial levels of accuracy. Although it was not assessed in this investigation, the conclusion follows from Norman and Goldberg's (1966) study that even greater levels of interrater reliability and criterion validity would have been expected had more target-relevant information been available to the raters.

What implications do these results have for the "semantic overlap" hypothesis? The answer to this question is unfortunately complicated by the rather vague manner in which this hypothesis has been stated. Perhaps the clearest version of this hypothesis is its extreme form, namely, that the perceived structuring of personality traits is due entirely to some form of linguistic similarity in word meanings employed in trait rating scales and that such relationships would be different or even nonexistent if these words were not used in the rating scales. Clearly, the present results tend to disconfirm this interpretation of the semantic overlap hypothesis. Verbal descriptors are by no means necessary in eliciting consistencies in behavioral predictions. Indeed, this hypothesis provides no basis for interpreting the almost identical patterning of behavioral predictions made with both verbal and nonverbal target information or rating formats. Clearly, predictions similar to those obtained in the verbal rating conditions are made in the total absence of explicit verbal information.

There are alternative weaker forms of the hypothesis that merit some consideration. These may be summarized as follows: (a) linguistic factors do not account for all of the expected covariation of behavior, but contribute substantially to such findings; (b) connotative attributes of trait descriptions, like desirability, account for a major portion of the variance in observations of personality; or (c) even nonverbal cues elicit common linguistic associates in judges that are semantically related in some form of verbal network. Ratings of personality made in a context devoid of any explicit verbal materials may be mediated by the implicit use of cognitively generated verbal labels.

With regard to the first alternative form of the semantic overlap hypothesis, that semantic processes account for substantial independent variance incrementing that obtainable from nonverbal processes, the data are generally nonsupportive. There were no significant differences in mean levels of correlation with the criterion between verbal and nonverbal target descriptions. The differences in accuracy between verbal and nonverbal rating scales, though statistically significant, were not substantial, a finding particularly noteworthy in view of the fact that the comparison was between unselected nonverbal items and highly selected verbal items. It is reasonable to assume that the psychometric characteristics of the PRF items are superior to those of the nonverbal illustrations. These scenarios were amassed without the consideration of important item properties such as content saturation, frequency of endorsement, and components of desirability, whereas the verbal items used have undergone stringent item selection procedures. In addition, one might expect language to provide a richer and more precise description of the behavior to be rated. This latter point is important in appraising the earlier criticisms of trait-oriented rating scales. Whereas earlier rating scales usually employed simple trait names or general descriptive phrases, the PRF items judged in the verbal rating conditions were largely descriptions of concrete behaviors. No one has explicated precisely the manner in which semantic or linguistic associative rules might conceivably apply to ratings of this type.

The second weaker semantic overlap hypothesis is that personality ratings are due to common connotative meanings such as desirability (evaluation), activity, and potency (Mischel, 1968). Two points might be raised regarding this interpretation. First, although these connotative components of meaning have often been studied in the context of verbal meaning, the Osgoodian formulation (Osgood, 1952) is general and does not depend on verbal meaning per se. In our study, it would be a simple matter for judges implicity to rate nonverbal stimuli for desirability. Whether verbal or nonverbal, no formulation is available for linking these connotative item attributes with the type of profiles comprising the empirical criterion for accuracy in this study. Second, the connotative attribute most prominently linked to ratings of personality, that is, desirability, when held constant statistically in our data, demonstrated no incremental effect on accuracy. Judgmental accuracy could not be attributed to a desirability stereotype, nor could it be accounted for as the prediction of normative item endorsement frequencies, since (a) the removal of base rates of endorsement did not alter the degree of association between the predictions and their respective criteria, and (b) the mean ratings for the two targets were approximately orthogonal.

To what extent are the results derived from nonverbal cues and nonverbal rating scales due to verbal mediation? This is a difficult question to answer, simply because such an hypothesis refers to covert, unobserved processes in accounting for empirical results. There are three relevant points here. First, this study addressed itself initially to semantic overlap between *explicit* verbal cues in ratings of personality. To our knowledge, no one has attempted to explicate the manner in which such supposed covert complex processes might operate. Second, if one might assume that these verbally mediated processes did occur, for example, between the processing of nonverbal personality descriptions and nonverbal ratings, one would expect some loss in fidelity in comparison with the situation in which verbal descriptions of personality would be rated nonverbally. (Verbal mediation would assume that the nonverbal cues would have to be coded verbally and entered into a semantic space, with a verbal personality inference made and this information transformed into a nonverbal rating. From this perspective, going from verbal cues to nonverbal ratings would be less subject to error, since access to the semantic space would be more direct.) Contrary to expectations from a verbal mediation hypothesis, accuracy is not attenuated going from nonverbal cues to nonverbal ratings. Similarly, going from nonverbal cues to verbal ratings is not less accurate than going from verbal cues to verbal ratings, contrary to expectations based on a verbal mediation hypothesis.

The third point to consider with regard to this question of verbal mediation concerns the lack of an effect for the order manipulation. It might be argued that if verbal mediation were to occur, the intervention of verbal material subsequent to the study of the nonverbal target description but prior to making the nonverbal judgments would expedite this cognitive process, thereby intensifying accuracy and consistency in the predictions of behavior. There are two reasons to expect greater fidelity on the nonverbal rating scales after, rather than before, the verbal rating scales have been filled out: (a) the verbal items would elicit covert verbal labels not evoked by the preceding nonverbal target description nor evident in the subsequent nonverbal illustrations; and (b) the process above would happen to a certain degree in all the subjects receiving common verbal material prior to their nonverbal judgments on the nonverbal target description (i.e., subjects in the second order conditions). Since the explicit labels and terms contained in the verbal rating scales would be constant for all subjects (whereas cognitively generated labels might not be), this would mean that the intervention of verbal material would serve to unify, across raters, the covert labels upon which the trait attributions may be predicated. In short, one would expect the introduction of explicit verbal material in a nonverbal rating context to have an incremental effect on inferential sensitivity under the verbal mediation hypothesis. However, there was no effect of order of ratings on rating accuracy or consistency.

Although it is clear that a verbal mediation hypothesis cannot readily account for our

major findings, we do not wish to imply that verbal processes are nonexistent in judgments of personality. Most natural languages, including English, are rich with trait descriptive terms. It would be silly to suppose that people did not sometimes use them. Clearly, research is needed on the conditions under which verbal processes contribute to judgments of others. Although such research may well demonstrate their presence, the present findings support the view that verbal information is neither necessary nor sufficient to account for major findings regarding the structure of perceived personality relationships.

In reconciling the data from this study with previous findings of the structure of personality ratings, one might extend the notion of a parallelism between verbal and nonverbal judgmental processes, which was originally developed to account for findings in the area of cognitive psychology (Paivio, 1975), to the area of person perception. Such a notion, which obviates the concept of verbal mediation, requires the acceptance of two networks of associatively linked entities, one being a network of verbal descriptors, and the other, a network of imaginal entities. Presumably, personality inferences would be based on either or both cognitive systems depending on the input modality, contextual cues, and requirements of the task. This dual coding approach "distinguishes between imaginal and verbal cognitive processes . . . [which are] independent but partly interconnected systems for encoding, storage, organization, transformation (i.e., reorganization), and retrieval of stimulus information" (Paivio, 1975, p. 148). Empirical studies have demonstrated that nonverbal, or imaginal, thinking "can be characterized by remarkable speed, accuracy, and flexibility of information processing" (p. 161).

Conclusions

From an experimental comparison of the use of nonverbal and verbal cues in a personality judgment task, and a reinterpretation of extant data, we may conclude that

1. Substantially reliable and accurate behavioral inferences can be obtained in a judgmental context devoid of explicit verbal materials.

2. The structure of judgments based on nonverbal cues corresponds closely to the structure of ratings obtained in a situation where verbal cues preponderate.

3. The data were not consistent with the interpretation that a process of verbal mediation accounted for the similarities between nonverbal and verbal personality inference.

4. Neither could the major findings of this study be attributed to the use of a common desirability stereotype or "generalized other" in the use of nonverbal and verbal cues. Statistical control of desirability and response base rates showed that they had no incremental effect on accuracy.

5. The data support the view that linguistic informational cues, relationships, and rating scales are neither necessary nor sufficient to account for observed consistencies in personality.

The Role of Category Accessibility in the Interpretation of Information About Persons: Some Determinants and Implications

Thomas K. Srull and Robert S. Wyer, Jr.
University of Illinois at Urbana-Champaign

Many personality trait terms can be thought of as summary labels for broad conceptual categories that are used to encode information about an individual's behavior into memory. The likelihood that a behavior is encoded in terms of a particular trait category is postulated to be a function of the relative accessibility of that category in memory. In addition, the trait category used to encode a particular behavior is thought to affect subsequent judgments of the person along dimensions to which it is directly or indirectly related. To test these hypotheses, subjects first performed a sentence construction task that activated concepts associated with either hostility (Experiment 1) or kindness (Experiment 2). As part of an ostensibly unrelated impression formation experiment, subjects later read a description of behaviors that were ambiguous with respect to hostility (kindness) and then rated the target person along a variety of trait dimensions. Ratings of the target along these dimensions increased with the number of times that the test concept had previously been activated in the sentence construction task and decreased with the time interval between these prior activations and presentation of the stimulus information to be encoded. Results suggest that category accessibility is a major determinant of the way in which social information is encoded into memory and subsequently used to make judgments. Implications of this for future research and theory development are discussed.

When individuals are asked to judge themselves or another person, they are unlikely to perform an exhaustive search of memory for all cognitions that have implications for this judgment. Rather, they are likely to base their judgment on some subset of these cognitions that is most readily accessible (Tversky & Kahneman, 1973, 1974). Using quite different research methodologies, Carlston (1977) and Lingle and Ostrom (in press) have both shown that once a judgment of a stimulus person has been made on the basis of new information, this judgment is subsequently used as a basis for later inferences about the person independent of the information upon which the judgment was originally based. Similarly, Ross and his colleagues (Ross, Lepper, & Hubbard, 1975; Ross, Lepper, Strack, & Steinmetz, 1977) have found that once a person has constructed an explanation of an event involving himself or another person, this construction, rather than the information that stimulated it, is used to predict the likelihood of future events. Each body of research therefore suggests that the most easily accessible cognitions about an object or event (i.e., those that have been acquired and used most recently) have a major influence on future judgments.

Similar considerations arise when a person

The present research was supported by U.S. Public Health Service Training Grants MH-14257 and MH-15140 to the first author and National Science Foundation Grant BNS 76-24001 to the second author. We thank Frank Costin for generously providing us with many of his stimulus materials. We would also like to extend our sincere appreciation to two anonymous reviewers, each of whom provided us with trenchant but very constructive criticism of an earlier draft of the manuscript.

is asked to interpret new information about a social stimulus. In many instances, the information one receives is ambiguous; that is, it can be interpreted in more than one way. For example, information that someone told his girl friend that her new hair style is unattractive could be interpreted, or *encoded,* as either "honest" or "unkind." Which encoding is actually made may depend upon which of the two relevant concepts (honest or unkind) is most easily accessible at the time the information is received (cf. Bruner, 1957). Once the behavior is encoded as an instance of one of these trait concepts, the implications of this encoding, rather than those of the original behavioral information, may be used as a basis for subsequent judgments about the person (Carlston, 1977; Higgins, Rholes, & Jones, 1977). If this is true, judgments of a person may often be affected substantially by rather fortuitous events that lead one or another concept to be more accessible to the judge at the time information about the person is initially received.

This paper reports two in a series of studies designed to investigate the possibility raised above and to explore its implications. In so doing, they supplement and extend an earlier study by Higgins, Rholes, and Jones (1977). These authors reasoned that if subjects were required to use trait terms in the course of performing one task, these terms would become more accessible and therefore more likely to be used to encode subsequent behavioral information about a person in an unrelated context. To test this hypothesis, subjects first performed a color-naming task that required them to remember four trait terms. In experimental conditions, the traits were all potentially applicable for encoding a normatively based set of behavioral descriptions (e.g., thinking about crossing the Atlantic in a sailboat), whereas in control conditions they were all inapplicable. Moreover, in some cases the four terms all had positive evaluative implications (e.g., "adventurous"), while in other cases they all had negative evaluative implications (e.g., "reckless"). As part of a second, ostensibly unrelated experiment, subjects read a story about a stimulus person that contained these behavioral descriptions. Subjects then both wrote a description of the target person in their own words and estimated how much they liked this person. Experimental subjects tended to describe the target person with trait terms that were the same as or synonymous with those to which they had been exposed in the color-naming task. In addition, their subsequent ratings of the target person were biased in the direction of the evaluative implications of these terms. In contrast, control subjects who were exposed to trait terms that were inapplicable for encoding the target's behavior did not vary systematically in either the evaluative implications of their free descriptions of the target or their ratings of him.

The findings of Higgins et al. provide intriguing support for the general hypothesis that once a concept is activated or "primed" as a result of its use for one purpose, its relative accessibility is enhanced, and its likelihood of being used to encode subsequent information increases. Moreover, the implications of the encoding, rather than those of the original stimulus material, are used as a basis for later judgments. Several additional questions are raised by these results, however. First, in the Higgins et al. study, subjects were primed with specific trait labels, each of which presumably represented a particular cognitive category or concept. To the extent that trait and behavioral concepts are interrelated in memory, however, the accessibility of trait concepts may also be increased by priming specific behaviors that exemplify these trait concepts. In this regard, it may be useful to conceptualize the representation of person information in memory in terms of schemata, or configurations of interconnected traits and behaviors at different levels of generality (cf. Cantor & Mischel, 1977). Such schemata may be hierarchical, with trait terms centrally located and behavioral instances of the traits more peripheral. Once a schema is activated, it may then be used to interpret and organize subsequent information (Bransford & Johnson, 1972; Lingle & Ostrom, in press). Thus, exposure to behavioral instances of a trait in one context may activate a schema associated with this trait, and the schema may then serve as a basis for inter-

preting subsequent behavioral information that is received in other contexts (Wyer & Srull, in press).

This reasoning implies that it is not necessary to prime the name of a trait in order to increase the likelihood that the schema associated with it will be used to interpret subsequent information. Rather, one needs only prime behavioral instances of the trait that are represented in the schema. It is conceivable, however, that several such instances must be primed in order to activate the schema itself. One reason for this is that behaviors are often ambiguous; that is, they can be considered instances of several different traits. To this extent, they are less likely to be interpreted as representative of any given trait when considered in isolation. Thus, it is reasonable to expect that the likelihood of activating a trait schema will increase with the number of behavioral instances used to prime it.

Once a trait concept or schema is activated as a result of exposure to representative behaviors, its accessibility, and thus its effect on the interpretation of subsequent information, is likely to decrease over time. This prediction is both intuitively reasonable and formally derived on the basis of several existing theoretical formulations. For example, Wyer and Srull (in press) have developed a model of social information processing in which the accessibility of a primed concept is postulated to decrease as a function of the number of other potentially relevant concepts used during the subsequent time interval. Since the likelihood of using at least one other potentially relevant concept becomes greater as the time interval increases, the likelihood of using the initially primed concept to interpret new information becomes correspondingly less.

Wyer and Carlston (1979) have formulated a model of person memory that also predicts this decrease. According to this formulation, which in many respects is similar to the semantic memory model of Collins and Loftus (1975), the residual "excitation" that remains at the location of a previously activated trait concept decreases over time once the concept is no longer used. As a result, increasingly greater amounts of excitation are required to reactivate the concept as time goes on, and the trait category is less likely to be invoked.[1] The two models therefore differ in that the first attributes the decrease in accessibility to be a function of interference effects (the likelihood of which increases over time), while the second attributes the decrease to be a function of time per se, independent of any interference produced by other concepts.

To summarize, then, the above reasoning implies that the accessibility of a trait schema, and therefore the likehood that it will be used to interpret new information, will increase with the number of schema-related behavioral concepts that have been activated prior to the receipt of this information but will decrease with the length of time between the activation of these concepts and acquisition of the new information to be interpreted. The present set of experiments tests these hypotheses.

The experiments reported extend upon the findings of Higgins et al. in one other important way. Specifically, Higgins et al. found that the accessibility of trait terms that were inapplicable for encoding the behavioral information did not affect subsequent evaluations of the target person. This suggests that priming does not have a direct influence on subjects' judgments of the target but affects these judgments only through its mediating influence on the interpretation of the target's behavior. Once the behavior has been encoded in terms of a given trait (e.g., "hostile"), however, and an overall impression of the target has been formed on the basis of this encoding, the target may then be ascribed other, evaluatively similar traits (e.g., "unintelligent") that are related only on the basis of subjects' implicit personality theories (Rosenberg & Sedlak, 1972). This possibility

---

[1] The effects of priming appear to dissipate very rapidly with the semantic tasks that are typically used to test the Collins and Loftus model. Wyer and Carlston's extension of the model does not postulate this rapid a decay of excitation, however. More important, the stimulus domain and judgment tasks to which the Wyer and Carlston model is theoretically applied are quite different from those considered by Collins and Loftus.

was also explored in the present set of experiments.

Method

Overview

Two experiments were run. The first investigated the effects of priming concepts related to hostility. The second was a conceptual replication in which concepts related to kindness were primed. The procedure used was the same in each experiment. Subjects first performed a "word comprehension" task in which they constructed sentences from sets of words. These sets were constructed so that each sentence completed would describe a behavior either related or unrelated to hostility (kindness). The total number of questionnaire items and the proportion of items related to the concept being primed were both systematically varied. Then, as part of a separate experiment on impression formation, subjects read a paragraph about a hypothetical target person who manifested a series of behaviors that were ambiguous with respect to the trait being primed. Judgments of both the target person and of individual behaviors were then analyzed as a function of the length of the priming questionnaire (30 or 60 items), the proportion of hostile (kind) priming items in the questionnaire (20% or 80%), and the time interval between completion of the priming task and the presentation of the target information (no delay, 1 hour, or 24 hours).

Ninety-six introductory psychology students (8 in each experimental condition) participated in Experiment 1 for course credit, and a different group of 96 students participated in Experiment 2.

Selection of Behavioral Descriptions

Experiment 1. To select behavioral descriptions that varied both in terms of the hostility they conveyed and in terms of the ambiguity of their implications, 43 subjects who did not participate in the main experiment were asked to rate a large pool of individual behaviors along a scale from 0 ("not at all hostile") to 10 ("extremely hostile"). From this pool were selected 5 behaviors that were judged to convey high hostility ($M = 8.08$) and 5 that were judged to convey low hostility ($M = .58$). In addition, 10 "ambiguous" behaviors were selected on the basis of two criteria: first, the mean hostility rating of each ambiguous behavior ($M = 3.99$) was lower than the mean rating of any behavior identified as hostile and higher than that of any behavior identified as nonhostile; second, the standard deviation of ratings for each ambiguous item was greater than the largest standard deviation of any item in either of the other two groups ($SD = 2.76$). The 10 ambiguous items were randomly divided into two groups of 5, and each group was then used to construct a vignette describing a hypothetical target person. In addition, all 20 behaviors were used as test items to be rated individually in a manner to be described.

Experiment 2. A procedure similar to that described above was used to select behavioral descriptions related to kindness. In this case, the mean ratings ($n = 40$) of the items selected as kind, ambiguous, and unkind were 8.71, 4.24, and .81, respectively. Again, the standard deviation of each ambiguous item was greater than the largest standard deviation of any item in the other two groups ($SD = 2.92$).

Procedure

Except where noted, the procedures described were identical in both experiments.

Administration of the priming task. Subjects, who were run in groups of four to eight, were greeted by a male experimenter. The experimenter introduced himself as a graduate student and stated that subjects had not actually been assigned to him but that the "real" experimenter had agreed to let him pretest a word comprehension test he was trying to develop. The exercise was described as a test of how people perceive word relationships based on their first immediate impressions. The task consisted of a number of items adapted from materials developed by Costin (1969, 1975). Each item consisted of a set of four words, and the subject's task was to underline three of the words that would make a complete sentence. The subject was told to complete each item as quickly as possible. Each item listed the words in random order and was constructed in such a way that the subject could form at least two possible sentences. In Experiment 1, however, each possible sentence formed from the hostile priming items (e.g., "leg break arm his") necessarily conveyed hostility while each item formed from other (filler) items (e.g., "her found knew I") did not. In Experiment 2, the filler items were identical, but each possible sentence formed from the kind priming items (e.g., "the hug boy kiss") conveyed kindness.

Although the effects of priming were expected to increase with the number of times an instance of the trait concept was primed, a more diagnostic test of these effects was constructed by varying both the total number of items in the questionnaire and the proportion of these items that was relevant to the trait concept. Specifically, subjects completed a total of 30 or 60 items, either 20% (6 or 12 items) or 80% (24 or 48 items) of which were related to the concept being primed. (Items of each type were distributed randomly throughout the questionnaire.) The influence of the number of priming items per se would then be indicated by significant effects for both of these manipulations. Moreover, the proportion variable should have a greater effect when the total number of questionnaire items is large than when it is small.

To avoid suspicion, all subjects within any given experimental session received a questionnaire of the

same length, but the proportion of priming items was varied. In addition, the particular priming items used in constructing the questionnaire were varied, so that pooled over subjects within each condition, each item occurred the same number of times.

Presentation of stimulus materials. After completing the priming task, the graduate student thanked the subjects for helping him. They were then turned over immediately to the "real" experimenter, told to return 1 hour later, or told to return 24 hours later. (In the latter two cases, subjects had previously been notified through the mail that they were scheduled for those times as well. The early dismissal from the first session was attributed to a small mix-up that prevented one of the planned experiments from being ready on time.)

The second experimenter (a female) then led subjects to believe that the scheduled experiment consisted of three separate and unrelated tasks. The first task (the only one relevant to the present article) was described as a task of impression formation. Subjects were asked to read a short vignette about a stimulus person (Donald) that described a series of events occurring during the course of one afternoon. Two vignettes, serving as stimulus replications, were constructed for use in each experiment. Each vignette contained a different set of five behaviors that were ambiguous with respect to their implications for the primed trait. These behaviors were embedded within other information that was irrelevant to the trait. For example, one of the vignettes used in Experiment 1, which described behaviors that were ambiguous with respect to hostility, was the following.

> I ran into my old acquaintance Donald the other day, and I decided to go over and visit him, since by coincidence we took our vacations at the same time. Soon after I arrived, a salesman knocked at the door, but Donald refused to let him enter. He also told me that he was refusing to pay his rent until the landlord repaints his apartment. We talked for a while, had lunch, and then went out for a ride. We used my car, since Donald's car had broken down that morning, and he told the garage mechanic that he would have to go somewhere else if he couldn't fix his car that same day. We went to the park for about an hour and then stopped at a hardware store. I was sort of preoccupied, but Donald bought some small gadget, and then I heard him demand his money back from the sales clerk. I couldn't find what I was looking for, so we left and walked a few blocks to another store. The Red Cross had set up a stand by the door and asked us to donate blood. Donald lied by saying he had diabetes and therefore could not give blood. It's funny that I hadn't noticed it before, but when we got to the store, we found that it had gone out of business. It was getting kind of late, so I took Donald to pick up his car and we agreed to meet again as soon as possible.

Similar vignettes that were ambiguous with respect to kindness, were used in Experiment 2.

In each case, subjects were asked after reading the vignettes to form an impression of the person described and then rate him along a series of trait dimensions, six of which (hostile, unfriendly, dislikable, kind, considerate, and thoughtful) were assumed to imply either a high or a low degree of hostility/kindness, and the others of which (boring, selfish, narrow-minded, dependable, interesting, and intelligent) were expected to be evaluatively loaded but descriptively unrelated to either hostility or kindness. These ratings were made along a scale from 0 ("not at all") to 10 ("extremely") and in each case included reverse scoring on half the items.

Ratings of individual behaviors. After rating the target person, subjects rated the hostility (in Experiment 1) or kindness (in Experiment 2) conveyed by each of the 20 individual behaviors selected on the basis of the pretest data described earlier. These ratings were made along a scale from 0 ("not at all hostile/kind") to 10 ("extremely hostile/kind").

Ratings of trait co-occurrence. Finally, subjects were asked to estimate the co-occurrence of hostility (in Experiment 1) and kindness (in Experiment 2) with each of the other 11 traits. Items were of the form "If a person is hostile [kind], how likely is it that he is ———?" and were rated along a scale from 0 ("not at all") to 10 ("extremely").

Postexperimental data. To check on the extent to which subjects might have had insight into the objectives of the experiment despite the several precautions taken to dissociate the priming questionnaire from the impression-formation task, subjects in Experiment 2 were asked to indicate which of the four tasks they performed during the experimental session(s) were most likely to be related to the same hypothesis. Following this question, they were also asked to indicate any other tasks they thought might be related.

Collection of Normative Data

To facilitate the interpretation of the expected priming effects, normative data were collected on the 20 behaviors used in each experiment. To avoid possible context effects associated with the large pool of behaviors originally tested, different groups of subjects rated the amount of hostility conveyed by each behavior used in Experiment 1 ($n = 28$) and the amount of kindness conveyed by each behavior used in Experiment 2 ($n = 34$) on scales ranging from 0 ("not at all hostile/kind") to 10 ("extremely hostile/kind"). These ratings were all made under neutral testing conditions and were later used for comparative purposes.

Results

Experiment 1

Preliminary analysis. The traits *unfriendly, dislikable, kind, considerate,* and

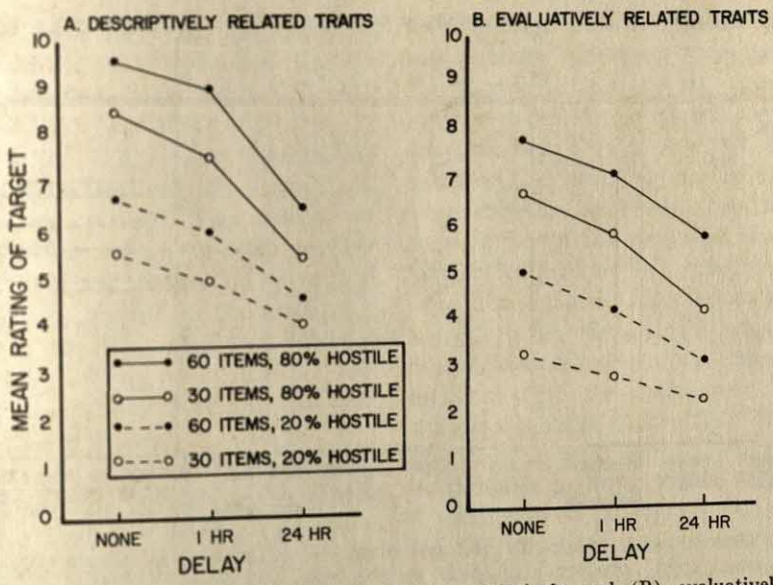

Figure 1. Mean ratings of target person along (A) descriptively and (B) evaluatively related traits to hostility as a function of questionnaire length, proportion of hostile priming items, and delay.

thoughtful were assumed to be denotatively related to the trait *hostile*. Ratings of the estimated co-occurrence of these traits with hostility, which ranged (after reverse scoring on the last three) from 8.79 to 8.98, indicate that they were all thought to covary with hostility to a substantial degree. Thus the six traits were summed across to produce a single index of the perceived hostility of the target. Similarly, ratings of the remaining six traits were summed after appropriate reverse scoring to provide a single index of the unfavorableness of the target along dimensions that are evaluatively loaded but not descriptively related to hostility, as evidenced by co-occurrence ratings ranging from 5.52 to 6.45.

Ratings of target person. Mean ratings of the target along both hostility-related dimensions and evaluative dimensions not directly related to hostility are shown in Figure 1 as a function of the length of the priming questionnaire, the proportion of hostile priming items, and the delay between completion of the priming task and presentation of the stimulus materials. Analyses as a function of these variables and the stimulus replication are relevant to several hypotheses. First, ratings of the target along both sets of dimensions were expected to increase with the number of times hostility-related concepts had previously been activated. Support for this can be seen in Figure 1, which shows that ratings of the target increased monotonically with the number of hostility-related items contained in the questionnaire. The hypothesis is supported statistically by significant main effects of both questionnaire length, $F(1, 72) = 123.74$, $p < .001$, and the proportion of hostile priming items, $F(1, 72) = 590.67$, $p < .001$. If the effect of priming is a linear function of the number of times hostility was previously primed, the effect of proportion should be greater when the questionnaire is long than when it is short. While the interaction of proportion and questionnaire length was not significant ($F < 1$), the pattern of results is consistent with predictions; specifically, when collapsed over delay conditions, the difference in the mean trait ratings of the target between low and high proportion lists was greater for the long questionnaire (2.70) than for the short questionnaire (2.51).

Second, the effect of priming was expected to decrease with the time interval between the priming task and presentation of the stimulus information to be encoded. The data shown in Figure 1 clearly support this hypothesis, which is tested statistically by the main effect

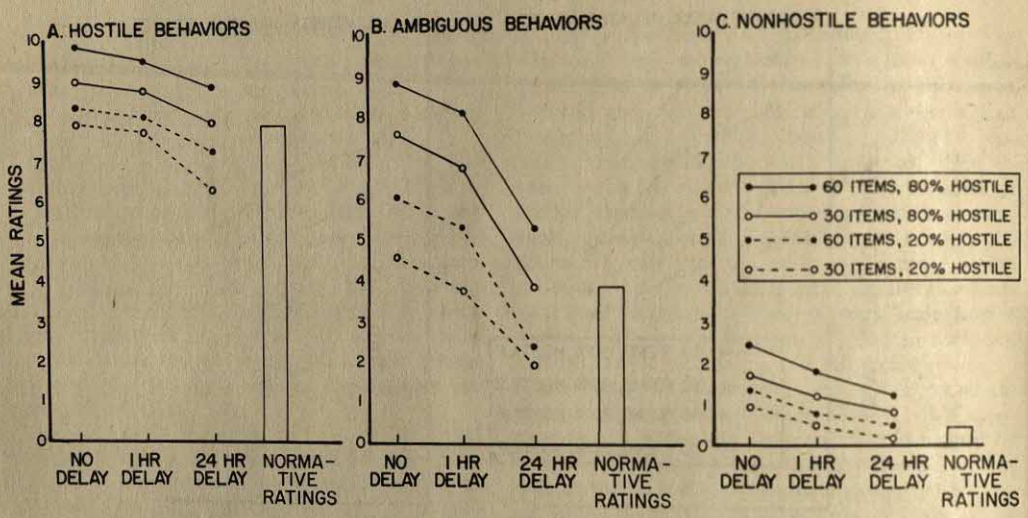

Figure 2. Mean ratings of (A) hostile, (B) ambiguous, and (C) nonhostile behaviors as a function of questionnaire length, proportion of hostile priming items, and delay.

of delay interval, $F(2, 72) = 133.32$, $p < .001$.[2] Figure 1 also suggests that the magnitude of the decrease in priming effects over time is a positive function of the number of times the category was initially activated (i.e., the number of relevant priming items in the questionnaire). Only the interaction of delay and proportion of priming items was statistically significant, $F(2, 72) = 8.30$, $p < .001$, indicating that the effect of delay increased with the proportion of priming items in the initial questionnaire. Since the number of relevant items presented differed more as a function of proportion than as a function of overall questionnaire length, the greater contingency of delay on the former variable is not surprising.

Finally, priming effects on judgments of hostility were expected to generalize to ratings along dimensions that are evaluative but related to hostility only indirectly through subjects' implicit personality theories. Data in the right panel of Figure 1 clearly support this hypothesis. However, these effects were not as pronounced as they were on judgments along dimensions that were descriptively related to the primed concept (left panel of Figure 1). This hypothesis is supported by significant interactions of trait type with both delay, $F(2, 72) = 5.13$, $p < .01$, and the proportion of hostile priming items, $F(1, 72) = 5.70$, $p < .05$. Specifically, the effect of delay interval on judgments of the target along descriptively related dimensions was greater ($M = 7.65$, 6.94, and 5.28 in the immediate, 1-hour, and 24-hour conditions, respectively) than its effect on judgments along evaluative but not descriptively related dimensions ($M = 5.77$, 5.00, and 3.90, respectively). However, the proportion of hostile priming items had less effect on hostility-related judgments ($M = 5.41$ and 7.83 under 20% and 80% conditions) than on evaluative judgments along other dimensions ($M = 3.49$ and 6.29, respectively).

Ratings of individual behaviors. The mean ratings of hostile, ambiguous, and nonhostile behaviors are plotted in Figure 2 as a function of experimental variables. Analyses of these data yielded an obviously significant effect of behavior type, along with the predicted main effects of delay, proportion of hostile priming items, and length of the priming questionnaire (in each case, $p < .001$). By far the greatest effects occurred on ratings of ambiguous behaviors, as evidenced by significant

[2] It should be noted that all of the results reported in this paper are based on analyses of variance that assume homogeneity of treatment–difference variances. The small positive bias that results when this assumption is not completely satisfied (see, e.g., Huynh & Feldt, 1970) would appear insignificant in relation to the general strength of the results.

interactions of behavior type with questionnaire length, $F(2, 144) = 65.64$, $p < .001$; proportion of hostile priming items, $F(2, 144) = 352.95$, $p < .001$; and delay, $F(4, 144) = 223.69$, $p < .001$. The 4-way interaction among these variables was also significant, $F(4, 144) = 3.38$, $p < .02$. This reflects the fact that the interaction among delay, number of priming items, and proportion of critical priming items was greater for the ambiguous behaviors than for the other two behavior types, $F(2, 72) = 4.79$, $p < .02$. In fact, this component accounts for 73.8% of the total interaction sums of squares.

The differences in ratings under the 24-hour delay conditions are sufficient to justify the conclusion that the priming task influenced judgments even after a fairly long time interval had elapsed. However, they do not indicate in an absolute sense whether the delayed ratings were positively affected by priming under all conditions. Evidence bearing on this question is provided by a comparison of these ratings with normative ratings of the behaviors made by subjects who were not exposed to the priming task. These normative ratings are also presented in Figure 2. Unfortunately, the comparisons are not easy to interpret. Subjects who completed priming questionnaires in which only 20% (6 or 12) of the items were hostility-related made *less hostile* ratings of both the hostile and ambiguous behaviors than subjects who received no priming at all. Taken at face value, this suggests that priming under these conditions had a negative effect after a delay of 24 hours. However, since comparable results did not obtain in Experiment 2 (see below) and such negative effects are difficult to account for theoretically, such a conclusion must be treated very cautiously pending replication. (Indeed, it seems more reasonable to attribute the finding to spuriously high normative ratings of the behaviors than to negative effects of priming.)

Experiment 2

Preliminary analysis. The traits *considerate, thoughtful, hostile, unfriendly,* and *dislikable* were assumed to be descriptively related to the trait *kind*. Mean estimates of the co-occurrence of these traits with kindness (after reverse scoring on the last three) ranged from 8.54 to 8.85, indicating that they were all thought to covary with kindness to a substantial degree. Ratings of the six traits were therefore summed across to produce a single index of the perceived kindness of the target. Ratings of the remaining six traits were also summed after appropriate reverse scoring to provide a single index of the perceived favorableness of the target along dimensions that are evaluatively but not descriptively related to kindness. Ratings of the estimated co-occurrence of these traits with kindness ranged from 5.69 to 6.24.

Ratings of target person. Mean ratings of the target person along dimensions both descriptively and evaluatively related to kindness are plotted in Figure 3 as a function of experimental variables. These effects are similar in most respects to those obtained in Experiment 1. The hypothesis that ratings would increase monotonically with the number of times concepts related to kindness were previously activated is supported by main effects for both questionnaire length, $F(1, 72) = 35.62$, $p < .001$, and the proportion of kind priming items in the questionnaire, $F(1, 72) = 158.67$, $p < .001$. Moreover, the effect of proportion was significantly greater when the questionnaire was long ($M = 4.54$ and 6.05 under 20% and 80% conditions) than when it was short ($M = 4.24$ and 5.18, respectively), $F(1, 72) = 8.85$, $p < .01$.

The hypothesis that priming effects would decrease over the time interval between the priming task and stimulus presentations was again strongly supported, $F(2, 72) = 47.79$, $p < .001$. Moreover, the magnitude of this decrease was greater when the proportion of kind priming items in the questionnaire was high than when it was low, $F(2, 72) = 19.66$, $p < .01$, and greater when the questionnaire was long than when it was short, $F(2, 72) = 5.98$, $p < .01$. These findings indicate that the effect of delay is a positive function of the number of times that kindness was initially primed.

Finally, the priming manipulations had very similar effects on ratings of both dimensions that are descriptively related to

kindness and those that were evaluative but descriptively unrelated. This again supports the hypothesis that once the target's behavior is encoded in terms of a trait, it will also be assigned other characteristics that are evaluatively associated with this trait. However, the effect of delay on ratings of descriptively related dimensions ($M = 5.94$, 5.15, and 4.54 in the immediate, 1-hour, and 24-hour conditions, respectively) was greater than for ratings of evaluatively related dimensions ($M = 5.23$, 4.88, and 4.29, respectively), $F(2, 72) = 3.61$, $p < .05$. Moreover, the effect of proportion was greater for descriptively related judgments ($M = 4.55$ and 5.87 under 20% and 80% conditions) than for evaluative judgments along other dimensions ($M = 4.23$ and 5.36, respectively). However, this difference was not reliable, $F(1, 72) = 1.54$, *ns*.

There are two related differences between these data and those obtained in the first experiment. First, the delay interval in Experiment 1 had an appreciable effect at all combinations of questionnaire length and proportion of critical priming items, whereas the effect of delay in the present experiment was negligible when the proportion of priming items was low, $F(2, 72) = 1.68$, *ns*. Second, the effect of the two priming variables after a 24-hour delay was pronounced in the first experiment, but was much less so in this study. In fact, neither questionnaire length ($F < 1$) nor proportion of kind priming items, $F(1, 72) = 3.12$, *ns*, had reliable effects after such a delay. In sum, these data suggest that a greater number of priming items was necessary to increase the accessibility of a schema associated with kindness than was required to increase the accessibility of a schema associated with hostility. Moreover, the accessibility of kindness-related concepts appears to decrease more rapidly over time than does the accessibility of concepts related to hostility.

Ratings of individual behaviors. Mean ratings of individual behaviors designated as kind, ambiguous, and unkind on the basis of normative data are shown in Figure 4 as a function of experimental variables. The effects of these variables are generally similar to their effects on ratings of the target person; that is, the estimated kindness of all three types of behaviors increased with both questionnaire length and the proportion of kind priming items contained in the questionnaire, each $F(1, 72) \geq 43.60$, $p < .001$, while decreasing as a function of the time interval between the priming task and making these estimates, $F(2, 72) = 51.73$, $p < .001$. Moreover, the effects of the time delay increased with both questionnaire length, $F(2, 72) = 6.75$, $p < .01$, and the proportion of kind priming items, $F(2, 72) = 25.75$,

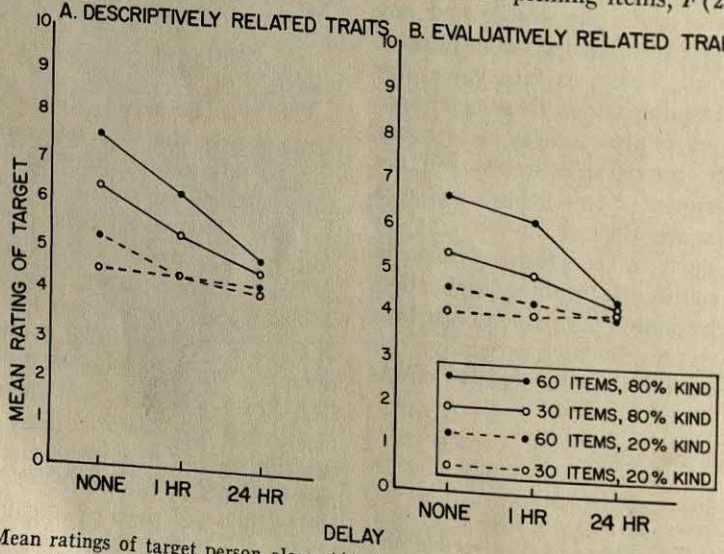

Figure 3. Mean ratings of target person along (A) descriptively and (B) evaluatively related traits to kindness as a function of questionnaire length, proportion of kind priming items, and delay.

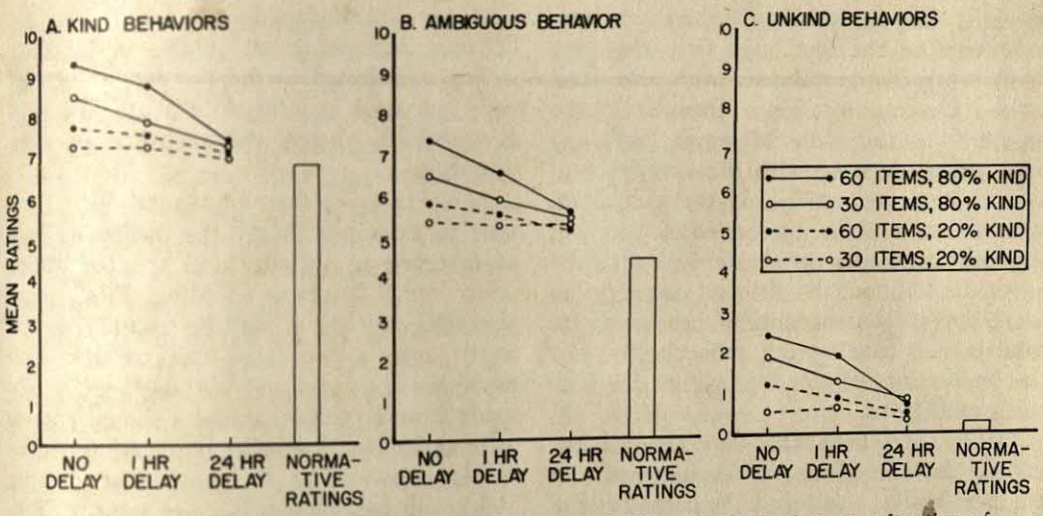

Figure 4. Mean ratings of (A) kind, (B) ambiguous, and (C) unkind behaviors as a function of questionnaire length, proportion of kind priming items, and delay.

$p < .001$. As in the case of target ratings, priming had virtually no effect when only 6 or 12 kindness-related items were involved, and the effect of priming after a 24-hour delay was negligible.

In addition to the above effects, there was an interaction between behavior type and the proportion of kind priming items, $F(2, 144) = 10.53$, $p < .001$. This interaction reflects the fact that the proportion variable had a greater effect on ratings of ambiguous items than on unambiguous ones, $F(1, 72) = 14.42$, $p < .001$. This component accounts for 74.5% of the total interaction sums of squares. Finally, there was also an interaction among behavior type, proportion of kind priming items, and delay, $F(4, 144) = 2.44$, $p < .05$, which is again attributable to the greater effect of experimental variables on ratings of ambiguous behaviors than on ratings of unambiguously kind or unkind behaviors, $F(2, 72) = 3.31$, $p < .05$. This component accounts for 73.9% of the total interaction sums of squares.

The mean normative ratings of each type of behavior under neutral conditions are also shown in Figure 4 for comparison. These ratings, unlike the corresponding ones in Experiment 1 (see Figure 2), are invariably below subjects' ratings in any one of the priming conditions. Thus, each level of priming increased the perceived kindness of all three types of behaviors. However, this effect was much less pronounced after a 24-hour delay than after either of the shorter delays.

Supplementary analysis. Despite the elaborate precautions taken to separate the priming and experimental tasks, a postexperimental questionnaire was administered to determine whether subjects had insight into their actual relatedness. Two findings suggest that subjects were not complying with any implicit demand characteristics. First, only 5 of 96 subjects thought the first (priming) task was related to any of the other three tasks performed during the course of the experimental session(s). Moreover, only 1 of these 5 connected the priming task to the subsequent impression-formation experiment. Thus, subjects were just as likely to relate the priming task to an objectively irrelevant experiment as to the ratings of actual concern. Since each of the four tasks was highly dissimilar, subjects appeared to be guessing randomly and to have no insight at all into the relationship of the two tasks.

Discussion

The two experiments reported in this paper are consistent in their implications for the processing of information about persons. Specifically, once a trait concept or schema is made more accessible by previous cognitive activity, the likelihood that the same schema will be used to encode new information is

increased. The accessibility of these concepts, and therefore the likelihood that they are subsequently used, increases with the number of times that instances of them have been activated in the past. Moreover, although these effects decrease with the time interval between their activation and the acquisition of information to be interpreted or encoded, they are sometimes detectable even after 24 hours. In addition, the effect of category accessibility on the encoding of behavioral information is much more pronounced when the implications of this information are relatively ambiguous.

Finally, once behavioral information is encoded, these encodings affect judgments of the person who manifested the behavior with respect to both the trait originally primed and other traits that are related to it only indirectly through subjects' implicit personality theories. The fact that these effects were typically less on judgments of the latter than of the former traits suggests that this generalizability is not simply due to a halo effect produced by exposure to "good" or "bad" concepts on the priming task. Moreover, this generalization process is very likely to be contingent upon the original encoding of the information about the person being judged. As Higgins et al. (1977) found, increasing the accessibility of a trait concept has little effect on later evaluations of a target person unless the concept is applicable for encoding the information about this person. Once the encoding takes place and an overall impression of the target is formed, however, it may then be used as a basis for inferring traits of the target that are unrelated to either the original behavioral information or the material in the priming task.

In combination, the present experiments and the earlier study reported by Higgins et al. suggest that category accessibility is an important mediator of social judgment processes. However, direct evidence of encoding was not obtained in the present study. Such evidence is suggested by Higgins et al., who found that only the priming of trait terms that were potentially applicable for describing the target's behavior affected subjects' later characterizations of him. Thus, primed traits that were evaluatively toned but inapplicable for describing the target's behavior had no effect. While similar data were not collected in the present study, the paradigm used is sufficiently similar to suggest tentatively that similar processes were operating.

At least two other approaches could be used to examine directly the mediating role of category accessibility and the conditions under which it affects encoding. First, reaction time procedures may be useful. For example, once a particular trait concept such as *hostile* is primed and is thus theoretically made more accessible, subjects should encode information with hostile implications more quickly, as well as be capable of making judgments based upon it more rapidly. Second, our analysis has assumed that encoding effects occur at the time the stimulus information is received. If this is true, priming trait concepts *after* presenting behavioral information about a target (i.e., after the information has already been encoded) should not have any effect on subsequent judgments of the person. Evidence that priming produces no effect under these conditions would provide clear evidence that priming effects are in fact mediated by the encoding of behavioral information.

The difference between the ultimate duration of priming effects obtained in this type of situation and those typically obtained with semantic and lexical decision-making tasks is striking. For example, the effects of priming a familiar noun category (e.g., "bread") on the time required to respond to other concepts that are closely associated with it (e.g., "butter") appear to dissipate in a matter of milliseconds (for a summary, see Schvaneveldt & Meyer, 1973). This suggests that the processes underlying these phenomena are quite different from those that underlie priming effects obtained in the experiments reported here. It also suggests that an "interference" interpretation of the sort postulated by Wyer and Srull (in press) may be more appropriate for describing the processing of complex social stimulus information than the spreading activation approach that is typically used to account for priming effects (cf. Collins & Loftus, 1975). On the other hand, the fact that the present effects

are sometimes still detectable after a period of 24 hours remains intriguing. It is possible that factors such as the experimental laboratory, the presence of the same fellow subjects, and other situational conditions provided a variety of relatively novel contextual cues that were rich enough to "reprime" the trait categories originally made salient. This possibility should also be explored in future research.

The generalizability of the main findings over experiments suggests that these effects are not unique to particular trait concepts or to traits at a given level of favorableness. The amount of priming required to activate different trait concepts appears to differ, however. In the first experiment, as few as six instances of hostile behavior were sufficient to activate the schema related to this trait and thus to affect subsequent judgments. However, many more instances of kindness were apparently required to increase the accessibility of a kindness-related schema. It is possible that this difference is due to unique characteristics of the two traits or the particular set of priming behaviors used. However, to the extent that these materials are representative of favorable and unfavorable traits, it would appear that favorable trait concepts are generally more difficult to activate using the present procedures. Impression formation research (e.g., Birnbaum, 1974; Wyer & Hinkle, 1976) has consistently shown that favorable information has less influence on judgments than unfavorable information does. One reason is that favorable information is typically more ambiguous (for direct evidence of this, see Wyer, 1974). In the present case, since favorable behaviors are socially desirable, instances of these behaviors may be considered less indicative of traits to which they correspond (cf. Jones & Davis, 1965). Therefore, when considered in isolation, these behaviors are less likely to activate a particular trait schema. This possibility may deserve further investigation using a broader sample of trait concepts than those considered in the present studies.

While the effects of manipulations of category accessibility decrease over the interval between the priming task and presentation of the information to be encoded, they appear to increase with the time interval between the presentation of this information and subsequent judgments (Higgins et al., 1977). These two effects should be distinguished. The likelihood that a trait category is accessed and used to interpret information should decrease over the time period since it was most recently activated, for reasons noted earlier. Different considerations arise in explaining the effect of a delay between the encoding of information and judgments. Immediately after exposure to the stimulus information, both the raw information and the encoded representation of it are easily accessible. To the extent that the encoding does not capture all the implications of the original information for the judgment to be made, the judgment may be based on a composite of both. However, the accessibility of the original input material may decrease more rapidly over time than the encoded representation of it, producing the increased effect of encoding reported by Higgins et al. Additional evidence of increased effects of encoding over time has been reported by Carlston (1977), and an investigation of comparable effects within the present paradigm may also be worthwhile.

A final issue to be considered concerns the way in which various target persons will be differentially affected by prior activations of a particular trait schema. The interpretation of information about persons is obviously an overdetermined process, and the accessibility of a particular trait schema is likely to be only one of several determinants. Wyer and Srull (in press) have proposed that schematic representations of specific individuals are built up on the basis of repeated experiences. In this regard, the effects of increased accessibility of a particular trait schema on the encoding of new information may be an inverse function of the amount of information already known about the target person. Thus priming effects may be most pronounced when the target person is previously unknown.

Negative and Positive Components of Psychological Masculinity and Femininity and Their Relationships to Self-Reports of Neurotic and Acting Out Behaviors

Janet T. Spence, Robert L. Helmreich, and Carole K. Holahan
The University of Texas at Austin

Negatively valued masculinity (M^-) and femininity (F^-) personality scales were developed to supplement the positively valued Masculinity (M^+) and Femininity (F^+) scales of the Personal Attributes Questionnaire (PAQ; Spence & Helmreich). M^- consisted of traits that had been judged to be (a) more typical of males than females, (b) undesirable in both sexes, and (c) agentic or instrumental in content. Two F^- scales were developed, both containing stereotypically feminine, undesirable traits, one set of traits referring to communionlike characteristics (F_C^-) and the other to verbal passive–aggressive qualities (F_{VA}^-). Significant sex differences in the predicted direction were found on all scales. In both sexes, low and typically nonsignificant correlations were found between parallel positive and negative scales, but highly significant negative correlations were found between positive and negative cross-sex scales. These findings provide additional evidence for the multidimensionality of masculinity and femininity. Scores on a self-esteem measure were positively correlated with M^+ and F^+, uncorrelated with M^-, and negatively correlated with the F^- scales. Different patterns of scores were associated with two types of problem behaviors. In both sexes, neuroticism was most highly correlated (in a negative direction) with M^+, and acting out behavior was most strongly correlated (in a positive direction) with M^-. The next highest correlation in both instances was with F_{VA}^-.

Studies of trait stereotypes (e.g., Rosenkrantz, Vogel, Bee, Broverman, & Broverman, 1968; Spence, Helmreich, & Stapp, 1974, 1975) have consistently demonstrated that the typical male and female are perceived as differing in a number of personality attributes. Males are reported to be higher than females in a cluster of characteristics reflecting personal competencies and goal orientation, whereas women are reported to be higher in a cluster of characteristics reflecting social–emotional sensitivity and an interpersonal orientation. The same differences in the personalities of men and women are frequently mentioned in the discussions of social-psychological theorists. Parsons and Bales (1955), for example, have distinguished between the extradomestic, instrumental role responsibilities assigned to men in most societies and the expressive, domestic role responsibilities assigned to women and have proposed that these differential role assignments are paralleled by underlying differences in the relative strengths of instrumental and expressive characteristics in the two sexes. Similarly, Bakan (1966) has identified two fundamental properties that characterize living organisms: a sense of *agency*, manifested in such characteristics as self-assertion, self-protectiveness, and self-aggrandizement, and a sense of *communion*, manifested in selflessness and a desire to be at one with others. Bakan has further identified agency as the "male principle," stronger in males than in females, and communion as the "fe-

male principle," stronger in females than in males.

It has frequently been assumed by psychological theorists that along with other attributes that differentiate the sexes and thus define "masculinity" and "femininity," these clusters of instrumental, agentic traits and expressive, communal traits are essentially incompatible and may thus be treated as endpoints of a single masculinity–femininity continuum. This proposition is joined with still a further assumption—that appropriate sex-typing has beneficial consequences for the individual, the masculine male and the feminine female exhibiting a higher degree of social adjustment and psychological health than those who deviate from the patterns of behaviors and psychological characteristics expected of their sex. More recently, these views have been challenged by a number of investigators (e.g., Bem, 1974; Block, 1973; Carlson, 1971; Constantinople, 1973; Spence & Helmreich, 1978; Spence, Helmreich, & Stapp, 1975) who have proposed that "masculine" instrumental characteristics and "feminine" expressive characteristics form separate dimensions that not only vary independently but also contribute positively to effective functioning in members of *both* sexes.

Data supporting the implications of these revisionist views have come from investigations employing two personality instruments, the Personal Attributes Questionnaire (PAQ; Spence & Helmreich, 1978; Spence, Helmreich, & Stapp, 1975) and the Bem Sex Role Inventory (BSRI; Bem, 1974), both of which contain separate Masculinity (M) and Femininity (F) scales. The PAQ M scale contains a series of socially desirable agentic traits, and the F scale a series of socially desirable communal traits. Although the BSRI is more mixed in content, the bulk of the items on the M and F scales may be similarly described.

Results obtained with these self-report instruments have consistently demonstrated sex differences on the M and F scales in the predicted direction, thus lending support to the common belief that the sexes differ in relative degree of agentic and communal characteristics. Within each sex, however, the correlation between scales has been found to be close to zero, and a number of individuals of both sexes have been found who score relatively high on both scales ("androgynous" individuals) or relatively low on both scales ("undifferentiated" individuals). The empirical data (e.g., Bem, 1977, Spence et al., 1975; Spence & Helmreich, 1978) also suggest that M scores, and to a lesser extent F scores, are positively associated with a number of indices of adjustment and social competence, irrespective of the sex of the individual. Thus "androgynous" individuals tend to be more socially effective than those who are sex typed.

It is critical to note that theoretical discussions of personality differences between the sexes have focused on socially desirable characteristics that purportedly contribute to execution of socially approved sex roles; similarly, studies of trait stereotypes have concentrated on identifying perceived differences between men and women in positively sanctioned attributes. In this same mode, the M and F scales of the PAQ and, to a large extent, of the BSRI,[1] are confined to the measurement of socially desirable traits.

Both observation and psychological theory suggest, however, that even within the category of agentic and communal traits, there are a number of "masculine" and "feminine" characteristics that are socially *undesirable* and have consequences for their possessors or those about them that may be deleterious. Bakan's (1966) theorizing is particularly relevant to this point. He proposes that a strong sense of agency, unmitigated by a sense of communion, is destructive to the individual and to society. Similarly, com-

---

[1] Ratings of the ideal man and woman on each of the BSRI items obtained by Gilbert, Strahan, and Deutsch (Note 1) indicate that on four of the F-scale items (shy, gullible, childlike, and soft-spoken), the means fell toward the nonfeminine pole for both sexes, thus suggesting their social undesirability. In addition, mean ratings of the two sexes fell toward the opposite pole on 6 of the 20 M and two of the 20 F items. As will be noted subsequently, items that corresponded to this pattern on the original PAQ (Spence et al., 1975) were assigned to a third, bipolar scale labeled masculinity–femininity (M–F).

munion must be mitigated by agency if the individual is to function effectively. The developmental task of males is thus to learn to balance masculine agency with some degree of communion, and of females, to balance feminine communion with some degree of agency.

In the present article, we will describe an extension of the PAQ to include scales tapping some of the socially undesirable components of psychological masculinity and femininity and will present data that explore the implications of these scales for self-esteem and two types of problem behaviors. Prior studies (Kelly, Caudill, Hathorn, & O'Brien, 1977; Heilbrun, Note 2) confirm the observation that negatively valued as well as positively valued attributes distinguish the sexes. A number of undesirable traits identified in these studies as being more characteristic of males than of females refer to the *absence* or *opposite* of desirable expressive, communal characteristics, whereas those identified as being more characteristic of females often refer to the *absence* or *opposite* of desirable instrumental, agentic characteristics. Setting up scales of undesirable attributes containing such items would be likely to provide no conceptual or empirical information not already provided by the existing PAQ M and F scales. Still other attributes identified in these studies are not easily classified into agentic versus communal categories and are of unknown theoretical significance. In expanding our instrument to include the negatively toned masculine and feminine attributes, it was our intent to develop scales that conceptually parallel the M and F scales, containing negatively valued masculine characteristics that reflect Bakan's "unmitigated agency" and negatively valued feminine characteristics that reflect "unmitigated communion." The procedures used to develop these scales and their content will be described in a later section.

Correlations between the original (socially desirable) M and F scales, it will be recalled, are close to zero and tend to be positive in sign. While similar relationships might occur between the negatively valued M and F scales, Bakan's (1966) theory suggests that stronger relationships that are *negative* in sign might be found between the original F scale (positive F or F^+) and the new, socially undesirable M scale (negative M or M^-). That is, these M^- characteristics (representing unmitigated agency) would tend to appear in those relatively lacking in socially desirable communal attributes. Similarly, a negative relationship might be expected between the positive M (M^+) and the negative F (F^-) scales, traits reflecting unmitigated communion tending not to appear in those with a healthy sense of self. Predictions about the relationships between parallel positive and negative scales (M^+ and M^-, F^+ and F^-) are more problematic. One might argue that those exhibiting one cluster of masculine or feminine traits would be more likely to exhibit a second cluster of sex-linked traits, or conversely, that those exhibiting a particular cluster of socially *desirable* characteristics would in general be less likely to exhibit socially *undesirable* characteristics. Perhaps, within a group of individuals, these opposing tendencies could be expected to cancel each other, leading to a minimal relationship between positive and negative scales belonging to the same sex-typed category.

In addition to obtaining normative and correlational data on the expanded PAQ to test these possibilities, we administered to the subjects the Texas Social Behavior Inventory (TSBI; Helmreich & Stapp, 1974), a measure of self-esteem and social competence, and a biographical questionnaire that inquired into the incidence of two types of problem behaviors: emotional distress of a neurotic nature, and sociopathic, acting out behaviors. In prior research (e.g., Spence & Helmreich, 1978), the TSBI has been found to be strongly correlated in both sexes with M^+ scores and moderately correlated with F^+ scores. Bakan's theorizing about the self-destructive implications of unmitigated agency and communion led to the expectation that considerably weaker if not negative relationships would be found between our measure of self-esteem and social competence and the negative EPAQ scales. A negative correlation with F^- (which reflects a lack of strong sense of self) seemed particularly likely.

In including the biographical question-

naire, we were exploring the possibility that different patterns of positive and negative M and F scale scores would be related to neurotic and acting out behaviors. Our expectations were clearest for the M scales. We anticipated that of all the scales, M^+ would be most strongly associated (in a negative direction) with emotional problems of a neurotic nature, that is, men and women exhibiting these difficulties would tend to be low in socially desirable agentic qualities. In conformity with prior studies, male students were expected to report more acting out behaviors than females, even with personality variables controlled. Within each sex, however, we predicted that M^- would show the strongest relationship with these behaviors in a positive direction, that is, men and women high in acting out would also tend to be high in the undesirable aspects of agency.

Method

Development of Masculinity and Femininity Scales

The development of the positive PAQ scales is described in detail elsewhere (Spence & Helmreich, 1978). Briefly, the instrument in its present form consists of 24 trait dimensions, drawn from those that had been judged in pilot work (Spence et al., 1974) to differentiate stereotypically between the typical man and woman. Ratings were also obtained of where the ideal man and woman fell on each trait dimension. These ratings were used to assign the items to three 8-item subscales. Masculinity (M^+) items were defined as those in which the mean ratings of the ideal man and woman both fell toward the stereotypically masculine pole; femininity (F^+) items were those in which the mean ideal ratings both fell toward the stereotypically feminine pole. Items were also selected to reflect agentic and communal traits for the M^+ and F^+ scales, respectively. A third group of items was identified, with items that were bipolar with respect to social desirability, that is, the ideal man fell toward the masculine pole and the ideal woman toward the feminine pole, and both were assigned to a separate scale labeled masculinity–femininity ($M–F^+$). The $M–F^+$ scale contains 2 agentic items (aggressive and dominant) and 6 items of more communal, expressive content describing emotional and personal vulnerability (e.g., cries easily, feelings easily hurt, high need for security).

Similar procedures were used in the development of the negative masculinity (M^-) and femininity (F^-) scales. Based primarily on pilot work by one of our students, Kirk Heilbrun (Note 2), with an item pool drawn largely from the Adjective Check List, a number of traits were identified whose presence was (a) judged to be socially undesirable for members of *both* sexes, (b) attributed more frequently to males than to females, and (c) agentic in content. The first two criteria were verified by submitting the items to additional groups of male and female college students, with instructions to rate the typical or the ideal member of each sex. In all instances, significant differences in the mean ratings of the typical male and female were obtained, whereas mean ratings of the ideal member of each sex fell toward the pole that indicated a relative *absence* of the stereotypically masculine trait. Agentic content was determined by ratings of the investigators and their graduate students. Eight items meeting these criteria were selected for the negatively valued masculinity (M^-) scale. (Eight items were chosen to equal the number of each of the socially desirable scales on the 24-item PAQ.) These items are: arrogant; boastful; egotistical; greedy; dictatorial; cynical; looks out only for self; and hostile. Each item is set up on a 5-point scale, with one extreme indicating a high degree of the trait (e.g., very arrogant) and the other a low degree (e.g., not at all arrogant).

The same procedures were used to identify trait items that are attributed more frequently to women than to men but at the same time are considered to be undesirable in both sexes. However, we were less successful in finding stereotypically feminine characteristics that appeared to reflect the excessive selfishness implied by negative communion. We abandoned our original goal as impossible to achieve fully and chose instead to investigate two sets of undesirable, feminine items (four items per set) because of the possibility that they would yield interesting data. The first cluster of four items comes close to unmitigated communion and is identified as F_C^-. The second cluster of four items describes a type of verbal passive–aggressiveness and is identified as F_{VA}^-. The items on the F_C^- scale are: spineless, servile, gullible, and subordinates self to others. Those on the F_{VA}^- scale are: whiny, complaining, fussy, and nagging. Items are set up on a 5-point scale, the extremes indicating a high and low degree of the trait.

Extended Personal Attributes Questionnaire (EPAQ). The negative and positive scales are combined to form a 40-item extended PAQ (EPAQ), each item being accompanied by a 5-point scale and scored from 0 to 4.[2] The M^+, M^-, and $M–F^+$ items are scored in a masculine direction and the F^+, F_{VA}^-, and F_C^- scales in a feminine direction.

[2] Copies of the scales and additional information on their psychometric properties can be obtained from the authors. The results of factor analyses are reported in Helmreich, Spence, & Wilhelm (in press).

Item scores are summed to obtain a total score for each scale.

Other Instruments

Texas Social Behavior Inventory. The 16-item short form of the TSBI (Helmreich & Stapp, 1974) was used as a self-report measure of self-esteem and social competence. Items are scored 0–4 and are summed to yield a total score.

Biographical questionnaire. The biographical questionnaire contained 39 items that asked subjects to indicate the frequency of certain kinds of behaviors or events at one or more periods of their lives (college, high school, grade school) and their current attitudes and feelings about certain aspects of their lives. After factor and other analyses, certain items were dropped, either because they had no predictive value (frequency of illness, level of school performance) or because their occurrence was too infrequent to provide useful data (appearance before juvenile court, involuntary psychological counseling). The remaining items were assigned to 10 scales, 8 of which described acting out or sociopathic behavior and 2 of which described emotional distress of a more neurotic nature. The acting out scales contained items referring to frequency of occurrence of (a) current use of alcohol and other drugs; (b) misdemeanors such as property destruction, shoplifting, and other minor thefts at three age periods (grade school, high school, and college); (c) lying at three age periods; (d) verbal and physical fights in grade school; (e) verbal fights in high school and college; (f) physical fights in high school and college; (g) school misbehavior in high school; (h) school misbehavior in grade school. These scales were positively correlated with each other in both sexes and entered into similar relationships with the EPAQ scales. They were therefore combined for purposes of data reduction into a single acting out scale.

The neurotic scales inquired primarily about current feelings. The first of these scales contained items referring to depression, certainty of life goals, satisfaction with social life, general life satisfaction, and voluntary seeking of professional help for psychological problems. The second neurotic scale contained items referring to frequency of feeling nervous, tense, fearful, and anxious. These scales were also significantly positively correlated and were combined to form a single neuroticism index.

Subjects and Procedures

The test battery, which included, in order, the EPAQ, the TSBI, and the biographical questionnaire, was administered to 220 male and 363 female students in introductory psychology courses at the University of Texas at Austin as part of a course requirement. The battery was given in mixed sex groups and was administered by a male and a female experimenter.

Results

EPAQ Scales

A series of t tests comparing the means of the male and female subjects indicated that the sexes differed significantly ($ps < .001$) in the predicted direction on all six scales. Except for the M–F$^+$ scale, the means of both sexes fell toward the socially desirable pole, which in the case of the negative scales indicated a relatively low degree of the indicated trait. On the M–F$^+$ scale, the mean for males fell slightly toward the masculine pole, and for the females, slightly toward the feminine pole. Since their values were highly similar to those previously reported (Spence & Helmreich, 1978), the means on the positive PAQ scales will not be given here. For the negative scales, the means for males and females, respectively, were 13.63 and 12.21 for M$^-$, 6.39 and 7.28 for F$_C^-$, and 5.28 and 6.48 for F$_{VA}^-$. (The maximum possible score is 32 for M$^-$ and 16 for F$_C^-$ and F$_{VA}^-$.)

Correlations between the EPAQ measures are shown for each sex in Table 1. The rs between the three original PAQ scales replicate those of previous studies (Spence & Helmreich, 1978), M$^+$ and F$^+$ having a slight positive correlation and M–F$^+$ having a substantial positive correlation with M$^+$ and a somewhat lower negative correlation with F$^+$. Turning to the negative scales, it will be noted that as with the positive scales, the values of the coefficients are similar for the two sexes. It will also be observed that the correlations between the two F$^-$ scales are positive but low, suggesting the desirability of scoring these two scales separately.

Particularly informative are the correlations between the parallel positive and negative scales. For M$^+$ versus M$^-$, and F$^+$ versus F$_C^-$, the rs are positive in both sexes, and for F$^+$ versus F$_{VA}^-$, the rs are both negative. However, even when the values are significant, they are small in magnitude, the highest being only .15. (The bipolar M–F$^+$ scale, scored in a masculine direction, has a somewhat higher positive correlation with M$^-$ than does M$^+$, .20 for males and .17 for females, $p < .05$.) For all practical purposes, then, the comparable positive and negative scales

may be treated as independent and may thus enter into very different relationships with other variables. These data also provide further reassuring evidence of a lack of contaminating social desirability response bias in the EPAQ scales; were such a bias systematically distorting subjects' responses, a substantial negative correlation would be expected between counterpart positive and negative scales.

As was expected, more substantial correlations, all significant and negative in direction, were found between the *cross-typed* positive and negative scales. Those high in M^+ thus tended to be low on both F^- scales. These same negative relationships were also found for the $M–F^+$ scale, the correlation between $M–F^+$ and F_C^- in both sexes being particularly marked. Similarly, those high in F^+ tended to be low in M^-. Finally, M^- showed a substantial positive correlation with F_{VA}^- and a negative but small correlation with F_C^-.

In previous studies we have found it heuristically useful to classify subjects jointly on their M^+ and F^+ scores by a median split method to reveal how M^+ and F^+ combine to influence some dependent variable. The present subjects were categorized into four groups by this method, using college student norms (Spence & Helmreich, 1978): Androgynous (above the combined male and female medians on both M and F), Masculine (above on M, below on F), Feminine (below on M, above on F), and Undifferentiated (below on both). Means were next determined for males and females in each PAQ category on the three negative scales. Simple analyses of variance indicated that for each sex and scale, significant differences ($p < .001$) occurred across categorical groups. Inspection of the means, shown in Table 2, suggests that in both sexes, M^+ and F^+ combine additively to determine M^-. That is, with M^+ having a slight positive correlation and F^+ a more substantial negative correlation with M^-, one would anticipate from an additive combination that the Masculine group would have the highest mean on M^-, followed by the Undifferentiated, Androgynous, and Feminine groups. This order obtained in both sexes. The data from the F^- scales also produced the ordering of PAQ groups predicted by an additive combination of M^+ and F^+, the one exception being several slight inversions for females on F_{VA}^-. In view of magnitudes of the underlying correlations, the latter result probably reflects sampling error. What should be noted about these orders is that

Table 1
Correlations of EPAQ Measures in Males and Females

Scale	1	2	3	4	5	6
1. M^+	—	.14	.50	.12	−.28	−.38
2. F^+	.09	—	−.30	−.33	−.09	.07
3. $M–F^+$	.45	−.29	—	.20	−.24	−.45
4. M^-	.10	−.47	.17	—	.40	−.09
5. F_{VA}^-	−.29	−.14	−.27	.45	—	.28
6. F_C^-	−.30	.15	−.40	−.14	.07	—

Note. EPAQ = Extended Personal Attributes Questionnaire. Males are above the diagonal, and females are below. For males, $df = 227$, $r_{.05} = .13$. For females, $df = 361$, $r_{.05} = .10$. M^+ = positively valued Masculinity Scale. F^+ = positively valued Femininity Scale. $M–F^+$ = positively valued Masculinity–Femininity Scale. M^- = negatively valued Masculinity Scale. F_{VA}^- = Feminine Verbal Aggressive Scale. F_C^- = Feminine Communion Scale.

Table 2
Means on the Negative Scales for Males and Females Classified by Category on M^+ and F^+

Negative scale	PAQ category: Undifferentiated	Feminine	Masculine	Androgynous
		Males		
M^-	14.00	10.39	15.01	12.87
M_{VA}^-	6.87	4.75	4.53	5.10
F_C^-	7.15	7.32	5.58	6.22
		Females		
M^-	13.93	10.31	16.59	11.74
F_{VA}^-	7.13	6.89	7.08	5.58
F_C^-	7.51	7.89	5.54	7.09

Note. PAQ = Personal Attributes Questionnaire. M^+ = positively valued Masculinity Scale. F^+ = positively valued Femininity Scale. $M–F^+$ = positively valued Masculinity–Femininity Scale. M^- = negatively valued Masculinity Scale. F_{VA}^- = Feminine Verbal Aggressive Scale. F_C^- = Feminine Communion Scale.

Table 3
Correlations between EPAQ Scales and Self-Esteem, Neuroticism, and Acting Out Measures for Males and Females

Scale	Self-esteem		Neuroticism		Acting out	
	Males	Females	Males	Females	Males	Females
M^+	.66***	.68***	−.53***	−.41***	−.09	−.01
F^+	.23***	.20***	−.06	−.06	−.17**	−.02
$M\text{-}F^+$	.39***	.37***	−.43***	−.27***	.03	−.02
M^-	.02	.00	.13	.19***	.26***	.18***
F_{VA}^-	−.16**	−.30***	.33***	.31***	.22***	.09
F_C^-	−.40***	−.25***	.24***	.04	.13*	.08

Note. EPAQ = Extended Personal Attributes Questionnaire. M^+ = positively valued Masculinity Scale. F^+ = positively valued Femininity Scale. $M\text{-}F^+$ = positively valued Masculinity–Femininity Scale. M^- = negatively valued Masculinity Scale. F_{VA}^- = Feminine Verbal Aggressive Scale. F_C^- = Feminine Communion Scale.
* $p < .05$. ** $p < .01$. *** $p < .001$.

they differ for each negative scale, so that no categorical group is uniformly highest or lowest. For each scale, however, the Undifferentiated group exhibits the highest or second highest amount of the undesirable masculine or feminine qualities, and the Androgynous group the lowest or second lowest amount.

EPAQ and Self-Esteem

In previous studies with the PAQ (Spence et al., 1975; Spence & Helmreich, 1978), it has been demonstrated that in both sexes all three scales are positively related to scores on the TSBI, used as a measure of self-esteem and social competence. Substantial correlations are found with M^+, and lower but highly significant correlations with $M\text{-}F^+$ and F^+. Inspection of the correlations obtained in the present samples of males and females, shown in Table 3, reveals values highly similar to those of prior investigations. As had been anticipated, different relationships were found with the negative scales. In both sexes, the correlations with the self-esteem measure are close to zero for M^- and significantly negative for the F^- scales. Particularly marked is the relationship with F_C^- in males ($r = -.40$).

To examine the joint contributions of the EPAQ scales to self-esteem, males and females were each divided into three self-esteem groups, those falling into the upper quarter, middle half, and lower quarter of their respective score distributions. Multivariate analyses of variance on the scales were then computed for each sex and were found to be highly significant in each sex ($ps < .0001$). Inspection of the pattern of means reveals that in both sexes, systematic trends occurred on all scales except M^-. Scores increased from low to high self-esteem groups on all three positive scales and decreased on the two F^- scales. Univariate Fs were significant ($ps < .01$) except in the case of males and F_{VA}^-.

EPAQ and Neuroticism

Scores on our measure of neuroticism and of self-esteem and social competence turned out to be negatively related (rs of $-.55$ and $-.36$ for males and females, respectively, $ps < .001$). Although it was not surprising to find that those who perceived themselves as being socially effective tended to report experiencing less anxiety, depression, and dissatisfaction than others did, the contents of the two scales (and the underlying psychological phenomena that they were designed to reflect) are not mirror images of each other. It was therefore anticipated that the relationships between the EPAQ scales and the TSBI would not necessarily be highly similar to those between the former and the neuroticism measure.

The correlations between neuroticism and EPAQ scores, reported in Table 3, showed

that this is indeed the case. As expected, the strongest relationship is with M^+ (*r*s of −.53 and −.41 in males and females). Smaller but significantly negative correlations are also found with $M\text{–}F^+$ (*r*s of −.43 and −.27). However, the correlations with F^+ are nonsignificant. Thus, expressiveness and interpersonal skills, as measured by F^+, appear to contribute beneficially to social competence and self-esteem but appear to be unrelated to the kind of emotional disturbances—anxiety, depression, and so forth—tapped by the neuroticism scale.

The three negative scales correlate positively with neuroticism in both sexes, with the largest relationship being found with F_{VA}^- (*r*s of .33 and .31). In females, M^- had a significant (but modest) correlation, whereas F_C^- did not. In males the opposite pattern was found: F_C^- had a significant negative correlation, whereas M^- was nonsignificant.

Next, the males and females were each divided into three neuroticism groups, those falling into the upper quarter, middle half, and lower quarter of their respective score distributions, in order to determine the conjoint contributions of the EPAQ scales. Multivariate analyses of variance on the scales were highly significant in each sex ($ps < .0001$). Inspection of the pattern of means and the univariate *F*s reveals that the high neurotic males are significantly lowest in M^+ and $M\text{–}F^+$ and highest in F_{VA}^- and F_C^-, with a nonsignificant elevation in M^-. High neurotic females are also significantly lowest in M^+ and $M\text{–}F^+$ (and nonsignificantly on F^+) and highest on the three negative scales. For women, however, the effects of M^- are highly significant, whereas those for F_C^- are not. It is possible that the presence of negative cross-sex-typed characteristics is more consistent with emotional disturbance than is the manifestation of sex-congruent negative attributes.

A final analysis was undertaken in which subjects were classified as above or below the median on M^+ and F_{VA}^-, the two scales showing the strongest correlations in each sex. (For this purpose the rounded mean of the medians of males and females on each scale was used as the cutting point.) The percentage of subjects in each neuroticism group showing the most negative constellation (low M^+, high F_{VA}^-) was computed. For males, the low M^+, high F_{VA}^- pattern was found in 4% of the low neuroticism group, 17% of the medium, and 47% of the high. The comparable figures for females were 20% low, 35% medium, and 61% high.

EPAQ and Acting Out Behaviors

Inspection of the acting scores indicated that in both sexes, the distributions were moderately skewed; few of the subjects (particularly females) admitted to having manifested these behaviors to any marked degree. The scores were therefore subjected to a *z* transformation, and statistical analyses performed on the transformed scores.

Pearson correlations between acting out scores and scores on the self-esteem and neuroticism measures were not significant in either sex. Correlations between acting out scores and scores on each of the EPAQ scales for each sex are shown in Table 3. As anticipated, the highest correlations are between acting out and M^-. In both sexes, the values are both positive and highly significant, the relationship being more marked in males than in females. (The mean acting out score for males is also significantly higher than that for females.) For females, no other correlation reached significance, although the signs are in reasonable directions. For males, a significant negative correlation is found with F^+ and a significant positive correlation with F_{VA}^- and F_C^-.

To determine the joint contributions of the EPAQ scales to acting out, males and females were divided into three acting out groups, these falling into the upper quarter, middle half, and lower quarter. Multivariate analyses of variance on the EPAQ scales were again computed for each sex and were found to be significant ($ps < .001$) in both sexes, although the results are stronger in males. Examination of group means and univariate *F*s indicated that scores in the high acting out groups are elevated significantly on M^- and F_{VA}^- in each sex. A similar linear pattern is also found on F_C^- but is significant only in females.

The subjects were also classified as being above or below the median on M^- and F_{VA}^-, the scales most strongly associated with acting out. Those exhibiting the most unfavorable combination, above the median on both M^- and F_{VA}^-, were then identified. In males, 63% of the high acting out group showed this high M^- and F_{VA}^- constellation, whereas only 30% of the moderate and 27% of the low groups were so classified. In females, the figures were 55% for high, 45% for medium, and 35% for low.

Discussion

On both the M^- and the two F^- scales, the mean self-report scores of men and women differed significantly in the direction predicted by the stereotype ratings. Despite the sex differences on the negative as well as the positive scales, the correlations between counterpart positive and negative scales were small and, typically, nonsignificant. Thus in neither sex did socially desirable and undesirable masculine or feminine traits tend to covary. Masculinity and femininity have typically been treated as if they were unidimensional constructs, those exhibiting a given cluster of masculine or feminine behaviors or attributes being assumed to possess other types of masculine or feminine characteristics to the same degree. The present results join a mounting body of evidence suggesting instead that the correlations among the empirically diverse categories of attributes and behaviors distinguishing the sexes are often low. When significant correlations *are* found between two clusters of masculine or feminine characteristics, the relationship may be attributable more to the particular characteristics involved than to the mere fact that they "belong" to the same sex-typed category.

The multifaceted nature of masculinity and femininity is further demonstrated by the pattern of correlations between cross-typed scales. The relationship between M^+ and F^+, as has repeatedly been found in prior studies, is low and positive in both sexes. More substantial negative correlations occur between cross-typed positive and negative scales, as was anticipated. Those high in undesirable agentic qualities, as reflected on the M^- scale, tended to exhibit a relatively low degree of desirable, interpersonally oriented qualities, as reflected on the F^+ scale. Similarly, those high in the socially desirable agentic qualities on the M^+ scale tended not to exhibit the verbal passive–aggressive qualities reflected in the F_{VA}^- scale or the self-subordinating qualities of the F_C^- scale.

Both positive and negative scales contribute to measures of self-esteem and social competence, neuroticism, and acting out behavior, although the patterns of relationships differ in the three types of measures. For self-esteem, all three positive scales, but particularly M^+, were positively related, and both F^- scales were negatively related to the criterion measure in both sexes. The correlation with M^-, however, was essentially zero. Although neuroticism tended to be associated with low self-esteem, F^+ was not significantly related to this type of emotional disturbance, although, as anticipated, substantial negative correlations were found between neuroticism and M^+ and $M–F^+$. All three negative scales were positively related to neuroticism, the highest correlation in both sexes being with F_{VA}^-.

The associations between acting out behaviors and the EPAQ scales tended to be somewhat weaker but of sufficient predictive value to be of potential practical as well as theoretical value. In both sexes, a high degree of acting out was most strongly associated with a high degree of M^- and, secondarily, with a high degree of F_{VA}^-. In both sexes, other scales also made significant contributions, but the pattern was not the same. Whether this discrepancy was due to chance or to genuine sex differences cannot be determined without testing additional samples.

A comment should be made about the relatively high percentage of men and women exhibiting the high M^- and F_{VA}^- constellation even in the low acting out groups (27% of the males and 35% of the females). This finding was to be anticipated. Manifestation of these undesirable masculine and feminine characteristics can take many forms less obviously antisocial than the behaviors tapped by the acting out measure. Additional information

about the individual and his or her life circumstances is required if their avenues of expression are to be predicted. Further, these negatively sanctioned behaviors are relatively infrequent. While our data suggest that individuals who exhibit sociopathic, acting out behaviors have a substantial probability of being high in M^- and F_{VA}^-, the probability that those who are high in M^- and F_{VA}^- also exhibit acting out behaviors should differ little from those with other personality constellations.

Although the results obtained with the neuroticism and acting out measures are promising, the samples were drawn from a nonclinical population, few of whose members exhibited any significant degree of problem behavior. Acting out was particularly mild, especially in women, and some of the behaviors (e.g., excessive use of alcohol and other drugs) may in some cases reflect escape from emotional distress rather than the manifestation of hostile, antisocial tendencies. We are currently extending our investigation of the implications of the positive and negative components of agency and communion to include clients of a student counseling center and adolescent and adult offenders whose activities have brought to them the attention of legal authorities. Assuming the replicability of the findings reported here, comparisons of these individuals with those from unselected populations might be expected to yield even more marked relationships with the EPAQ scales.

Motives for Social Comparison: The Construction–Validation Distinction

Russell H. Fazio
Indiana University

It is suggested that informational social comparison can be motivated by two different concerns: (a) an interest in obtaining from others any information about the entity that they have at their disposal and that the individual lacks or (b) an interest in obtaining information about the validity of one's judgment by determining if that judgment derives from one's personal biases or from the qualities of the entity. A comparison act motivated by the former concern is termed *construction* and by the latter is termed *validation*. The results of Experiment 1 suggest that a construction process occurs only when one's perceived level of information is low and others might possess additional information about the object. Two additional experiments examined the impact of agreement and disagreement from sources similar or dissimilar on a relevant attribute. Experiment 2 examined whether the judgments of each of these others are attributed largely to the other's similarity/dissimilarity or to the amount of information about the entity that the other is thought to possess. Experiment 3 examined the implications of the attributional patterns obtained in Experiment 2 for choice of comparison other under motives to construct vs. validate. The two motives were found to lead to differing preferences regarding choice of comparison other.

As individuals attempting to understand, predict, and exercise some control over a rather complex social environment, we are often interested in how our judgment of some object compares with others' judgments of that object. Such a proposition suggests that social comparison is desired and useful when one is in need of information about the adequacy of one's judgment (cf. Festinger, 1954; Goethals & Darley, 1977; Jones & Regan, 1974). The more important the judgment, the more likely that such informational social comparison will occur.

The present research focuses upon informational social comparison and investigates the proposal that such comparison can be motivated by two quite different concerns.

1. Sometimes we are interested in obtaining from others any information about the object that they have at their disposal and we lack. The goal of this process, which shall be termed *construction,* is simply the collection of information about the object—information that may be useful in constructing a judgment of the object.

2. A second concern that can motivate informational social comparison is an interest in testing the validity of one's judgment—what shall be termed a *validation* process. The individual wants to know whether she/he has processed and integrated the available information properly. Would others, given the same information, reach the same judgment? Or has she/he been unduly influenced by some personal idiosyncrasy? Naturally, the individual hopes that the answers to these questions lead to the conclusion that she/he is correct, that is, she/he hopes to achieve confirmation.

This article is based upon a doctoral dissertation submitted to the Department of Psychology of Princeton University. The author thanks Joel Cooper, chairman of the dissertation committee, for his thoughtful supervision of this research project, and the other members of the committee, John Darley and Ron Kinchla, for their helpful suggestions.

The construction–validation distinction is based upon the sort of information that the individual is seeking. Construction involves information about the object; validation concerns information about one's judgment of that object. (The distinction is similar to one drawn by Mettee & Smith, 1977, who note a difference between the discovery and construction of reality, i.e., construction, and the confirmation of already existing reality concepts, i.e., validation.) An analogy to two types of research may serve to clarify the distinction further. Often, research is conducted for exploratory purposes and in order to generate hypotheses. A few intuitions may guide such research, but the main purpose is not to test those intuitions but to collect data that can help one to form hypotheses. This type of investigation is analogous to the construction process. The validation process corresponds to research in which an empirical test of a hypothesis is conducted. The researcher seeks to test the validity of his or her hypothesis.

Just as a researcher might first conduct an exploratory investigation and then an empirical test of a hypothesis, an individual might first be concerned with construction and then with validation. That is, the two processes are likely to occur in sequence. A person may first desire information about the entity so that he or she can construct a tentative judgment of the entity. He or she may then seek to test the newly formed hypothesis empirically via a validation process. If validation is achieved, then the informational social comparison process will have come to a successful conclusion. If it is not achieved, the individual is likely to decide that she/he is in need of more information about the entity. The person may return to a construction process in order to discover what "facts" he or she has yet to consider. The person may evaluate this newly acquired information, construct a more accurate opinion, and then seek to validate that opinion.

It is our contention that the construction–validation distinction is critical to an understanding of informational social comparison. It shall be argued that construction and validation processes are very different, and three experiments suggesting this will be reported. Not only do concerns with construction versus validation diverge as a function of relevant variables, but choice of comparison other differs, given motives to construct vs. validate.

Experiment 1

Experiment 1 examined what variables might determine the extent to which an individual is concerned with construction versus validation. It was hypothesized that an individual would be most interested in construction and least interested in validation when the individual believed that she/he lacked information and believed that the other people available for comparison might possess a greater amount of information.

In order to examine social comparison processes, an experimental task of sufficient difficulty to prompt a need for information was required. Furthermore, the task needed to be one that permitted a simple and plausible manipulation of perceived level of information. For these reasons, the autokinetic effect was chosen as the experimental task. From the work of Sherif and his associates (e.g., MacNeil & Sherif, 1976; Sherif, 1935), it is clear that estimating the distance that the dot of light "moves" is a difficult and ambiguous task. In addition, perceived level of information could be easily manipulated by leading subjects to believe that they had been assigned to a condition in which they would or would not be provided with additional information about the distance that the light moves. Half of the subjects were provided with bogus information about the light's movement, whereas the other subjects were not.

Although subjects participated in the experiment individually, they were each led to believe that three other subjects were also present. The amount of information about the light that these supposed others might possess was manipulated as the second factor in the design. Half of the subjects were told that they and each of the supposed other subjects would be *individually* assigned to an information condition. The other half were told that each *group* would be assigned to a condition.

If the possibility that the available others possess more information does exist, as in the individual assignment conditions, then a construction motive may become operable. The lower a person's perceived level of information, the more that person may attempt to gather information from the available others (i.e., to construct). A subject in the group assignment conditions was led to believe that everyone possessed the same level of information that he or she had. This equivalence is predicted to undermine the construction motive, since it is not possible to collect additional information about the light. However, assignment to this condition should lead to a corresponding increase in a desire to validate one's judgment. Given whatever information upon which the subject has based his/her judgment, can she/he find confirmation of that judgment? Thus, desires for construction versus validation are predicted to be jointly dependent upon perceived level of information and individual versus group assignment. Subjects in the no information – individual assignment condition should exhibit construction versus validation interests that differ from the interests displayed in each of the other conditions.

Once the two independent variables, perceived level of information and assignment, had been manipulated, observations of the autokinetic effect began. During one particular series of trials, the subject was informed of the judgments of each of the supposed others. These bogus responses were constructed so as to manipulate agreement. One of the supposed others was shown to consistently agree with the actual subject, whereas the other two consistently disagreed. For another series, subjects were ostensibly to be formed into pairs, and the members of a pair were to discuss their judgments prior to reaching a decision about the distance that the light moved. Ratings of the extent to which each of the supposed others was desired as a partner served as the main dependent variable.

As argued earlier, subjects in the group assignment conditions have no opportunity to gain information for the construction process. However, they may well have a desire to validate their judgments. Validation implies choice of the agreeing other as a partner; she/he provides confirmation of one's own judgment. Thus, within the two group assignment conditions, regardless of the subject's perceived level of information, the agreer should be strongly preferred as a partner.

The perceived level of information variable should, however, have an impact upon partner selection within the individual assignment conditions. We have argued that construction tendencies should be most apparent for subjects with no information. Hence, these subjects will presumably desire to have as a partner someone who has more information about the light's movement. The agreeing other may be agreeing simply because she/he, too, is suffering from a lack of information. The disagreers, however, may be disagreeing because they have more information at their disposal than the subject has. As a result of these possibilities, preference for the agreer as a partner should be relatively low within this no information – individual assignment condition. For subjects with additional information, the need to gather more information (i.e., the desire to construct) should be weaker, and the desire to validate stronger, than for those subjects with no information. Hence, preference for the agreer as a partner should be stronger among subjects with, than among subjects without, additional information.

Method

Subjects

Forty Princeton University freshmen, naive to the true nature of the autokinetic effect, participated individually in the experiment for a payment of $1.50. Subjects were randomly assigned to one of the four conditions. The data from 2 subjects—1 from each of the group assignment conditions—were discarded. In one case the subject questioned the veridicality of the supposed other subjects' judgments. In the other, the subject did not perceive sufficient movement to permit the creation of one of the disagreeing responses. The final sample consisted of 10 subjects in each of the individual assignment conditions and 9 in each of the group assignment conditions.

Procedure

After making a few introductory comments, the experimenter informed the subject that a total of

four individuals would be participating in the experimental session. (This statement was the first of a number of steps that were taken to establish the plausibility of the presence of the fictitious group members.) Depending upon the punctuality of the subject's own arrival, the experimenter also commented upon how many of the (fictitious) others had already arrived. The subject was then ushered into an enclosed booth and instructed to read the materials that had been placed there earlier. While the subject read, the experimenter opened and closed doors at the appropriate times so as to lead the subject to believe that all three of the other subjects had arrived.

The materials that had been placed in the subject's booth described the study's supposed purpose and experimental design. The study purported to concern "the perceptual judgment of motion and distance" and was said to consist of three series of trials, "simulating three different ways in which judgments are often made." During Series 1, each individual was to make independent judgments about the distance the light moved. During Series 2, individual judgments were again to be made, but at the end of each trial the subject was to be informed of each of the other subject's responses. The third series was labeled a "coalition series" during which pairs of subjects would discuss their judgments. This conversation was supposedly to occur via a set of earphones and a microphone located in the booth. Subjects were told, "as much as possible, we will allow you to choose your partner."

Subjects also read that in order to investigate "how varying levels of information affect the accuracy of people's judgments," each subject would be assigned to one of three information levels for the duration of the experiment. On each trial, the experimenter would purportedly select a point within a distribution of distances specially prepared for that trial and would set a dial that would dictate the distance that the light moved. The information levels were said to relate to the distributions that the experimenter was ostensibly employing. The three conditions were described as: (a) a no information condition, in which subjects were to be provided with no additional information about the light's movement; (b) a partial information condition, in which subjects were to be provided with the interquartile range of the distribution of distances across all trials in the experiment; and (c) a complete information condition, in which subjects were to be given the interquartile range of the distributions for each and every trial of the experiment. Interquartile range was defined for the subject.

Assignment manipulation. One of two paragraphs followed the description of the information conditions. Half the subjects, those who had been randomly assigned to the individual assignment conditions, read the following paragraph.

> Each of you will be placed in one of these three conditions on a random basis. Thus, you may personally have at your disposal more or less information than the other people in the experiment.

For subjects in the group assignment conditions, the paragraph read:

> Each group of subjects in the experiment is randomly placed in one of these three conditions. Thus, whereas each of you in this experimental group will have the same amount of information, you and the other subjects in this group may have at your disposal more or less information than other groups in the experiment.

Once sufficient time had elapsed for the subject to read the materials and once the experimenter had feigned the arrival of each of the supposed other subjects, the experimenter began a series of private interviews with the actual subject and each of the supposed others. These interviews were conducted in the order of the subjects' purported arrival. To maintain and bolster the impression that three others were present, the experimenter opened the booth door for a supposed other. He then loudly requested that the person follow him, noisily moved the chair in the booth about, walked to the nearby interview room, and slammed the door shut behind himself. After allowing about a minute to pass, the experimenter noisily returned the supposed subject to the booth and closed the booth door. This procedure was repeated until all the supposed subjects had been "interviewed."

Perceived level of information manipulation. During the interview of the actual subject, the experimenter answered any questions that the subject had. He also made certain that the subject understood the descriptions of the three series and the three information conditions. The remainder of the interview concerned the information manipulation. The experimenter handed the subject a sheet of paper describing the condition to which the subject had been assigned. For half the subjects, this sheet simply read, "You have been randomly assigned to the NO INFORMATION condition." For the remaining subjects, the sheet stated, "You have been randomly assigned to the PARTIAL INFORMATION condition" and informed the subjects that the interquartile range of the distances the light would move was 2 to 6 inches. From pretesting, these figures had been determined to be within the range of distances subjects would perceive in the experimental setting. No subject was assigned to a complete information condition. Subjects were only led to believe that such a condition existed to ensure that the partial information subjects did not feel so informed that they would have no need to engage in social comparison.

Once the interviews had been completed, observations of the autokinetic effect began. The far wall of each booth contained a one-way mirror through which the subject observed the light in the next room. The light was located approximately 10 feet from the actual subject's mirror. For each trial the

light was illuminated for a period of 10 seconds. After each of the three trials in Series 1, the subject recorded a judgment of the distance to the nearest half-inch.[1] After each trial of Series 2, the subject also recorded a judgment. In addition, the subject wrote the judgment in large numerals on a blank sheet of paper and then held the sheet up to the mirror so that the experimenter could record each response. The experimenter walked from mirror to mirror and supposedly recorded the judgments of each of the subjects. Purportedly, he then made four copies and distributed one copy to each subject. Again, in order to maintain and bolster the deception that three others were involved, the experimenter made it appear that he was collecting a judgment from the occupant of each booth and that he was handing each subject a copy of the responses. This same procedure was followed for each of the three trials of Series 2.

Agreement manipulation. The supposed responses of the other subjects were fabricated in such a manner that one other subject generally appeared to agree with the subject and the two others generally disagreed. One disagreer (the positive disagreer) consistently perceived more movement than the subject; the other (the negative disagreer) reported observing less movement. On the first trial, the agreer was reported to have perceived 1/2 inch more movement than the subject, and the disagreers 2 inches more or less movement. On Trial 2, the agreer's response was 1/2 inch less than the subject's and the disagreers' responses were 1 inch more or less than the subject's. For Trial 3, the agreer's judgment was 1/2 inch more and the disagreers' 1 and 1/2 inches more or less than the subject's own response. All subjects were identified only by the booth identification letter (A, B, C, or D). The actual subject was always Subject B. For each subject, the location of the agreer, positive disagreer, and negative disagreer was randomly determined.

Dependent variables. After receiving the feedback for Trial 3 of Series 2, subjects were asked to complete a "Partner Selection Form" for Series 3. As a forced-choice measure, subjects were requested to select one other subject as a partner. In addition, in order to "accommodate all four of you as well as possible" and "in order to settle any conflict in partner selection that might occur," subjects were asked to rate the degree to which they would like to have each of the other subjects as a partner. These ratings were made on an 11-point scale where 0 indicated "definitely do not" prefer to have a particular subject as a partner and 10 meant "very much" prefer to have that person as a partner.

While the experimenter ostensibly reviewed the partner selection forms, subjects were asked to complete a short questionnaire. Two scales involved assessments of the degree to which construction and validation concerns were related to the subject's choice of a partner.[2] The first item asked subjects, "To what extent did you choose the partner you chose because he/she is likely to provide you with helpful information about the distance the light moves?" The second item read, "To what extent did you choose the partner you chose because he/she is likely to confirm and support your own judgments about the distance the light moves?" Each of these ratings was made on a 0–10 scale where 0 was labeled "not at all a consideration in my choice" and 10 "very much a consideration."

The last page of the questionnaire contained a check on the agreement manipulation. Subjects were asked to rate "how similar the responses of each of the other subjects were to your own responses during Series 2?" on a 0–10 scale where 0 was labeled "not at all similar" and 10 was "very similar". It should be noted that these agreement assessments were made while the subjects still had at their disposal the sheets that displayed each of the supposed subjects' judgments. Thus, this manipulation check measures only whether subjects could understand and correctly interpret the feedback when directly asked to do so. It in no way served as a memory check.

When the subject had completed the questionnaire, the experiment was terminated. The subject was carefully probed for suspicion with the aid of a postexperimental questionnaire. All deceptions were revealed, and the purpose of the study was explained to the subject.

Results

Manipulation Check

Responses[3] to the check on the manipulation of agreement suggest that the manipu-

---

[1] After each trial, the subject also indicated how certain he or she was of his or her judgment of the distance that the light moved. For each subject, the mean of the subject's three ratings during Series 1 (i.e., prior to any feedback) was computed. On a scale where 10 indicated extreme certainty and 0 reflected being not at all certain, the overall mean across all subjects was 4.25, suggesting that subjects were sufficiently uncertain to desire social comparison. An analysis of variance on these data revealed no significant differences between the conditions, however. Possibly, a floor effect was encountered; no information subjects may have been reluctant to admit any greater uncertainty.

[2] These scales were preceded by an open-ended measure in which subjects were asked to explain the reasons for their partner choices. The data from two judges who rated the extent to which each response indicated a concern with construction versus validation display the same pattern as the direct scale assessments. The same is true in Experiment 3. Details can be found in Fazio (1978).

[3] Two subjects, one from each of the individual assignment conditions, neglected to complete the manipulation check items.

Table 1
Mean Partner Preferences in Experiment 1

Perceived level of information and assignment	Agreer	Disagreer	
		Positive	Negative
No			
Individual	5.70	6.30	4.40
Group	8.11	4.22	4.22
Partial			
Individual	7.80	5.70	4.70
Group	8.11	6.56	2.67

Note. The higher the mean, the more that supposed other was desired as a partner.

lation was accomplished successfully. A 2 (No vs. Partial Information) × 2 (Group vs. Individual Assignment) × 3 (Agreer vs. Positive Disagreer vs. Negative Disagreer) analysis of variance, with the last factor as a repeated measure, revealed a strong effect-of-the-agreement variable, $F(2, 64) = 159.12$, $p < .001$. Furthermore, a contrast of the mean rating of the agreer ($M = 6.64$) with the average of the ratings of the two disagreers ($M = 4.21$) was highly significant, $t(64) = 17.72$, $p < .001$.

Partner Selection

Table 1 presents the mean preferences for each of the three others as a partner. A 2 × 2 × 3 analysis of variance revealed a main effect of the agreement variable (agreer $M = 7.43$, positive disagreer $M = 5.69$, negative disagreer $M = 4.00$), $F(2, 68) = 28.54$, $p < .001$. This general preference for the agreer is more characteristic, however, of the subjects in the group assignment condition than of those in the individual assignment condition, as is evidenced by a significant interaction between the assignment and agreement factors, $F(2, 68) = 4.12$, $p < .025$. As predicted, however, this two-way interaction is qualified by a significant higher order perceived level of information by assignment by agreement interaction, $F(2, 68) = 4.88$, $p < .02$. A preference for the agreer over the disagreers was apparent in each condition except the no information – individual assignment condition. In accordance with the conceptual framework proposed earlier, when others possibly had more relevant information and one's own perceived level of information was low, the agreeing other was not as strongly desired as a partner. Further confirming the hypotheses is the fact that multiple comparisons (by means of the least significant difference test) reveal that the agreer was preferred significantly less in the no information – individual assignment condition than in each of the other three conditions.

The forced-choice data display much the same pattern as the rating data. The proportion of subjects in each condition who chose the agreer as a partner (no information/individual = .50, partial information/individual = .90, no information/group = 1.00, partial information/group = .89) was noted, and these proportions were analyzed via an arcsin transformation (cf. Langer & Abelson, 1972). The analysis revealed a significant interaction between the perceived level of information and assignment variables, $z = 2.47$, $p < .02$. Subjects in the no information – individual assignment condition chose the agreer as a partner relatively less frequently than did the other subjects.

Motive for Comparison

Table 2 presents the mean ratings of desire for construction and validation in each condition. The data were analyzed as a 2

Table 2
Mean Construction and Validation Scores in Experiment 1

Perceived level of information and assignment	Construction	Validation
No		
Individual	7.00	3.80
Group	3.89	8.33
Partial		
Individual	5.20	6.00
Group	5.22	6.11

Note. The higher the mean, the more construction or validation was desired.

(Perceived Level of Information) × 2 (Assignment) × 2 (Construction/Validation) analysis of variance, with the last factor as a repeated measure. The analysis revealed an interaction between the assignment and construction/validation factors, $F(1, 34) = 6.82$, $p < .02$. More importantly, the predicted three-way interaction was also statistically significant, $F(1, 34) = 6.41$, $p < .02$, indicating that the reported motive for comparison was jointly dependent upon one's perceived level of information and the possibility that others possessed more information.

It should be noted that comparisons between construction and validation means within any given condition do not achieve statistical significance, with the exception of the no information – group assignment condition. Given that it is impossible to determine in advance whether the no information situation is sufficently lacking in information about the light's movement to produce a "pure" desire for construction, the present framework can only predict that the perceived level of information variable will affect desires to construct versus validate in a relative sense. The predictions call for differential construction versus validation interests when the no information – individual assignment cell is compared to each of the other cells. A series of interaction contrasts suggests that this is the case: for the comparison with the no information – group assignment condition, $t(34) = 3.65$, $p < .001$; with the partial information – individual assignment condition, $t(34) = 1.96$, $p < .10$; with the partial information – group assignment condition, $t(34) = 1.95$, $p < .10$.[4] Given that these measures of motive for comparison occurred after partner selection, these subsidiary data should be interpreted cautiously, however.

Discussion

The results of the experiment provide some support for the conceptual framework that was outlined earlier. Only when perceived level of information was low *and* the available others might possess more information were construction concerns relatively more apparent than validation concerns. Under these conditions, it appears that it may be advantageous to discover *why* another person disagrees. The disagreeing other may possess some useful information about the object. In contrast, individual assignment subjects whose perceived level of information was relatively high expressed little or no interest in discovering the reasons for another's disagreement. Rather, these subjects reported a relatively strong desire to confirm their own judgments and displayed a greater preference for the agreer than did no information subjects.

As the numerous interaction effects between the assignment and information variables show, the effects of perceived level of information differ under group versus individual assignment conditions. When the available others definitely possessed no more or less information than the subjects did, construction motives were thwarted. As a result, the interactive effect that was observed within the individual assignment conditions (no information subjects desiring construction more and validation less than did partial information subjects) is not apparent within the group assignment conditions. If anything, the data in the group assignment conditions tend in the reverse direction, with no information subjects desiring validation more and construction less than did partial information subjects, $t(34) = 1.65$, $p < .11$.

Regardless of the reported motives, subjects in both group assignment conditions displayed a strong preference for the agreer as a partner. One possible reason for this preference is a relatively greater concern for validation. Choosing an agreer, however, could reflect many possible concerns, including either validation or self-esteem enhancement. In fact, a number of researchers have drawn a distinction between informational and self-esteem motives for social comparison (e.g., Gruder, 1977; Hakmiller, 1966; Latane, 1966; Singer, 1966; Thornton & Arrowood, 1966). Experiments 2 and 3 more

[4] Each of these interaction contrasts reached a conventional level of statistical significance on the data from the open-ended measures of construction and validation.

closely address this issue of validation and its distinction from self-esteem processes.

Experiment 2

Goethals & Darley (1977) have suggested that two variables—agreement and similarity—may play a critical role in the selection of a comparison other. They invoked various attributional principles (Kelley, 1967, 1973) to note that a person seeking to determine whether his or her belief is correct wishes to determine whether his or her opinion is entity based (whether it accurately describes the entity) or whether it is person based (whether it derives from his own biases). Someone similar on attributes affecting the belief may agree simply because she/he is similar and is subject to the same biases that the individual is prone to. Correspondingly, disagreement from a dissimilar other can be attributed to the person's dissimilarity on the crucially relevant attribute.

Disagreement from a similar source and agreement from a dissimilar source appear to be more meaningful. If a similar other disagrees, the person's confidence that his opinion is entity based must decrease. Since the other is similar on the relevant factors, it would be difficult to attribute the discrepancy to the internal characteristics of that other. A dissimilar other who agrees, on the other hand, provides strong confirmation that one's belief is an accurate evaluation of the entity (cf. Goethals, 1972; Goethals & Nelson, 1973). Here is a person with wholly different biases who arrives at the same conclusion. The judgment which receives confirmation from a dissimilar other must, then, be due to the compelling qualities of the entity in question.

Experiment 2 examined whether attributions of this sort do actually occur. Subjects were asked to make causal attributions as to why each of four others (a similar and a dissimilar agreer and a similar and a dissimilar disagreer) agreed or disagreed with him. The predictions were: (a) the similarity/dissimilarity dimension would be assigned a greater causal role in determining the judgments of the similar agreer and the dissimilar disagreer than in determining the judgments of the similar disagreer and the dissimilar agreer and (b) the amount of information possessed would be assigned a greater causal role with respect to the judgments of the similar disagreer and the dissimilar agreer than with respect to the judgments of the similar agreer and the dissimilar disagreer.

Method

Subjects

Eighteen Princeton freshmen participated for a payment of $3.00. In the experiment, subjects were randomly assigned to the no or partial information conditions. One subject's data were discarded because the subject failed to understand how to complete the scales, leaving 9 subjects in the no information condition and 8 in the partial information condition.

Procedure

In a first session, all subjects were administered two paper and pencil tests. The first three-page, 18-item test was presented as a measure of one's depth perception ability. The test actually consisted of gestalt completion problems. Each item presented an incompletely and vaguely drawn picture. The subject's task was to identify the picture and to label it. The second test, presented as a measure of lateral perception, was also three pages and 18 items long. Each item presented an assortment of geometric figures. Subjects had to select which of five possible answers accurately displayed the smaller target figures in an arrangement that formed one larger figure.

Similarity manipulation. In order to provide subjects with feedback that was likely to confirm their own perceptions as to how well they had performed on the two tests, the number of items that the subject completed in the allotted time was counted for each test. These two numbers were placed on each of four graphs of page size, where two points of the abscissa were labeled *depth* and *lateral perception,* with the ordinate (8 inches in length) simply labeled *score.* A line connecting the two points represented the subject's profile. In addition, each graph presented the supposed scores of one other person. This other was identified by a letter that was to correspond to that person's booth identification letter during the second session. One similar other was shown to have a profile that was approximately ½ inch higher than the subject's on the depth perception test and ½ inch lower on the lateral perception test. Another profile showed the remaining similar other to be ½ inch lower than the subject on depth perception and ½ inch higher on lateral perception. The dissimilar others were portrayed by profiles with points 2 inches higher

or lower than the subject's. One dissimilar other was shown to have scored much better than the subject on depth perception and much lower on lateral perception, whereas the other was portrayed as having the reverse pattern. In this way, all the subjects were displayed as having approximately the same overall ability and differing on the specific components.

The procedure employed in the second session was virtually identical to that in the individual assignment conditions[5] of Experiment 1 and need not be repeated in detail. After reading the materials in his or her booth, the subject was ushered into the next room for the interview with the experimenter. During this time, the subject's questions were answered and the subject was notified of his or her information condition. The experimenter then handed the subject the test profiles and described how the graphs could be read. The experimenter further remarked that, whereas the perception of motion and distance involved both lateral and depth perception cues, people approach the perception of motion and distance with different styles. In this way, the profiles were presented as reflecting a dimension that was related to the task at hand (cf. Goethals & Darley, 1977; Zanna, Goethals, & Hill, 1975).

Following "interviews" with each of the supposed subjects, the autokinetic effect trials began. After each trial of Series 2, the subject received the bogus judgments of each of the supposed other subjects. One similar and one dissimilar other were portrayed as generally agreeing with the subject and the remaining similar and dissimilar others as generally disagreeing. These bogus judgments were presented via the same scheme used in Experiment 1. For half the subjects, the similar and the dissimilar others who had scored higher than the subject on the depth perception task were shown to agree with the subject, and the two others who had scored lower, to disagree. For the other half of the subjects, this pattern was reversed. Furthermore, for half the subjects, the similar agreer and the dissimilar disagreer were displayed as having seen more movement than the subject whereas the similar disagreer and the dissimilar agreer perceived less. For the other half of the subjects, the pattern was reversed such that the latter two individuals perceived more movement, and the former two less. Together, then, there were four possible arrangements of the others' responses. Approximately, one-quarter of the subjects in each condition received each of the possibilities. This "arrangement variable" produced no main or interactive effects on any of the variables assessed and accordingly receives no further consideration in this report.

Following Series 2, subjects were informed that they would be completing a questionnaire in which they would assess the reasons for the other subjects' judgments during Series 2. Subjects were asked to assess the importance of each of three dimensions in determining other subjects' judgments. The dimensions were the other's perceptual style, the amount of information the other possessed, and circumstances. Following Stevens and Jones (1976), the assessments were made on two sets of scales. The first set explicitly forced upon the subject the interdependence that is presumed to exist among the three dimensions. The subject was instructed to allocate a total of 100 points among the three possible reasons for the other subject's agreement or disagreement with his or her own judgments. A dimension was to be given a point value that reflected its judgments. Under the first listed dimension, "the subject's perceptual style," two options appeared: (a) "the similarity of the subject's perceptual style to my own" and (b) the "dissimilarity of the subject's perceptual style to my own." The subject was to choose (a) or (b), whichever he or she considered the most appropriate, and then assign the dimension a point value. Under the second listed dimension, "the amount of information the subject had about the light's movement," two options were also listed: (a) "the subject's lack of information" and (b) "the subject's possession of information." Again, the subject was to select the more appropriate option and assign the factor a point value. The third dimension listed was "the particular circumstances of the subject's observations" (e.g., the angle at which the subject viewed the light, his or her mood and attentiveness, etc.).

The second set of scales did not force any interdependence upon the subject. Instead, the subject rated the importance of the particular dimension on an independent scale. As the two sets of scales revealed the same effects, only the data from the interdependent scales shall be presented. The interested reader is referred to Fazio (1978) for a detailed presentation of the data from the set of independent scales.

Following completion of the scales, subjects were carefully probed for suspicion and were thoroughly debriefed.

Results

Subjects allocated a total of 100 points to the three attribution dimensions of perceptual style, information, and circumstances. Each dimension was assigned a point value that reflected its importance in determining the other person's judgments. Table 3 presents the means for each dimension. Because the value of one rating is perfectly determined by the sum of the other two ratings, only the perceptual style and information

---

[5] It was decided to run only the individual assignment conditions because perceived level of information was found to exert an influence in Experiment 1 only within the individual assignment cells.

Table 3
Means on Each of the Attribution Scales in Experiment 2

Attributional dimension and perceived level of information	Similar		Dissimilar	
	Agreer	Dis-agreer	Agreer	Dis-agreer
Perceptual style				
No	67.78	31.67	31.11	61.11
Partial	61.25	43.13	43.75	55.63
Information				
No	15.00	35.00	47.22	18.33

No	17.22	32.22	21.67	20.56
Partial	17.50	20.63	17.50	21.25

Note. The higher the mean, the more importance assigned to that dimension.

dimensions were analyzed. A 2 (No vs. Partial Information) × 2 (Similar vs. Dissimilar) × 2 (Agreer vs. Disagreer) multivariate analysis of variance revealed a strong Similarity × Agreement interaction, $F(2, 14) = 8.16$, $p < .005$. Perceptual style was viewed as more important in determining the judgments of those others whose responses were congruent with their perceptual style (the similar agreer and the dissimilar disagreer) than in determining the judgments of the incongruent others (the similar disagreer and the dissimilar agreer), univariate interaction $F(1, 15) = 13.60$, $p < .005$. Least significant difference tests revealed that similar agreers ($M = 64.52$) were perceived as having been affected by their perceptual style significantly more than were similar disagreers ($M = 37.40$). Likewise, dissimilar disagreers ($M = 58.37$) were thought to have been affected by perceptual style significantly more than were dissimilar agreers ($M = 37.43$). A univariate analysis of the information data revealed a Similarity × Agreement interaction such that the amount of information possessed was assigned a greater causal role in determining the judgments of the incongruent others than in determining the judgments of the congruent others, $F(1, 15) = 16.99$, $p < .001$. Similar disagreers ($M = 37.25$) were thought to have been affected by the information dimension significantly more than were similar agreers ($M = 18.13$), and dissimilar agreers ($M = 42.99$) were perceived as having been affected significantly more than were dissimilar disagreers ($M = 20.73$). No multivariate or univariate interactions with perceived level of information approached statistical significance.[6]

The results confirm Goethals & Darley's (1977) attributional analysis. Relative to similar disagreers and dissimilar agreers, similar agreers and dissimilar disagreers were perceived as having been influenced by perceptual style. The judgments of similar disagreers and dissimilar agreers, on the other hand, are thought to emanate more from their possession of information than are judgments of the two remaining others. Furthermore, at least in the present setting, these attributional patterns appear to hold regardless of one's perceived level of information and one's motive for social comparison.

Experiment 3

Experiment 3 examined the implications of the attributional patterns found in Experiment 2 for actual choice of comparison other. From an attributional perspective, only a similar disagreer and a dissimilar agreer are potentially meaningful and informative comparison choices. It was predicted that these two sources differ in the degree to which they appeal to a person concerned with construction versus a person concerned with validation.

The person seeking construction perceives himself to suffer from a lack of information with which to "construct reality." Experiment 1 suggested that those seeking construc-

[6] These data were also analyzed in terms of scores coded for the direction of the various attributions. The analysis showed that the judgments of similar agreers and dissimilar disagreers were attributed largely to similar and dissimilar perceptual styles, respectively. The disagreement of a similar other and the agreement of a dissimilar other were attributed largely to the others' possession of information. No significant effects were observed on the circumstances scale. The analysis is reported in detail in Fazio (1978).

tion are more interested in discovering why some other person disagrees with them than are those people seeking validation. These differential preferences should be particularly evident when it is clear that this disagreeing other is similar on relevant attributes. Given this similarity, this other person should be agreeing, unless he is aware of some information that the subject himself lacks. To the extent that the partner preferences of no information subjects in the present experimental situation are dictated solely by construction concerns, the similar disagreer should be more strongly preferred than any of the available others. At a minimum, no information subjects should display a greater preference for the similar disagreer than partial information subjects, since the former group should be relatively more interested in construction and less interested in validation than the latter group.

Analogously, it can be hypothesized that those seeking validation should display a greater preference for the dissimilar agreer. Such a person, having what he considers sufficient information to "construct reality," is interested in determining the validity of his judgment. The dissimilar agreer is particularly useful in this regard. Agreement from a dissimilar source informs the individual that he has based his judgment upon the "facts" and not upon any person biases. Thus, to the extent that partial information subjects are concerned solely with validation, they should display a stronger preference for the dissimilar agreer than for any of the three others. Given their relatively greater interest in validation over construction, partial information subjects should, at a minimum, prefer the dissimilar agreer more than no information subjects.

Method

Subjects

Twenty-four Princeton freshmen participated for a payment of $3. Subjects were randomly assigned to no or partial information conditions. The data from 2 subjects were excluded from the analysis because the subjects were skeptical of either the agreement or the similarity feedback. The final sample consisted of 11 subjects in each of the two conditions.

Procedure

With the exception of the dependent variables, the procedure was identical to that employed in Experiment 2. After the manipulations had been accomplished, subjects in Experiment 3 completed the same dependent measures as in Experiment 1. Partner selection ratings were made for Series 3. Measures concerning motivations behind partner selection were also completed.

These subjects then completed checks on the manipulations of similarity and agreement. On a 0 (very dissimilar) to 10 (very similar) scale, subjects rated "how similar the depth and lateral perception test results of the other subjects were to your own test results." Also, on a 0 (strongly disagreed) to 10 (strongly agreed) scale, subjects rated "the degree to which the responses of each of the other subjects during Series 2 agreed or disagreed with your own responses." It should again be noted that subjects were not expected to have committed all the similarity and agreement information to memory. The profiles and judgments of each of the others were still available to the subject. These measures merely served to check whether subjects could correctly interpret the information provided about the others.

Results

Manipulation Checks

Similarity and agreement. Subjects in Experiment 3 completed two measures designed to check that the similarity and agreement information was understandable to both these subjects and those in Experiment 2. A 2 (No vs. Partial Information) × 2 (Similar vs. Dissimilar) × 2 (Agreer vs. Disagreer) analysis of variance, with the last two factors as repeated measures, was conducted on each of the manipulation checks. A strong main effect of the similarity variable was found on the similarity ratings (similar $M = 8.41$, dissimilar $M = 2.23$), $F(1, 20) = 491.25$, $p < .001$. Correspondingly, the agreement manipulation strongly affected the ratings of the degree to which the others' judgments agreed with the subject's own judgments (agreer $M = 8.21$, disagreer $M = 3.41$), $F(1, 30) = 141.42$, $p < .001$. Thus, subjects were capable of drawing the desired distinctions among the supposed four others present.

Certainty. Perceived level of information has been presumed in this report to relate to certainty. The more information an individual believes himself or herself to possess about the object in question, the more certain that per-

Table 4
Mean on Each Certainty Measure in Experiments 2 and 3

Measure	Experiment	Perceived level of information: No	Perceived level of information: Partial
Difference ratio	2	.84	.68
	3	.84	.72
Symmetry	2	.57	.21
	3	.38	.26

Note. On both measures, the higher the mean, the greater the uncertainty.

son is apt to feel about his/her judgment of that object. Because of subjects' reticence to admit of extreme uncertainty, direct measures of certainty tend to be relatively unpowerful. In Experiment 1, no effects were found with a direct measure of certainty (see Footnote 1). Thus, Experiments 2 and 3 involved an indirect measure of certainty. In addition to their best estimates of the distance that the light moved, subjects were asked to indicate the maximum and minimum possible distances that the light moved.

From this information, a two-component index of certainty was derived:[7] (a) the mean (across the three trials of Series 1) of the ratios of the difference between the maximum and minimum estimates to the best estimate and (b) the proportion of the three trials on which the subject placed his or her best estimate symmetrically between the minimum and maximum judgments. For each component, higher scores reflect less certainty.

Multivariate analysis of the data was performed in order to ask the question "Is there any linear combination of the difference ratio and the symmetry measure which discriminates between the conditions?" A 2 (Experiment 2 vs. 3) × 2 (No vs. Partial Information) multivariate analysis of variance revealed a main effect of the perceived level of information variable, $F(2, 34) = 4.66$, $p < .02$, with no main effect of experiment ($F < 1$) nor an interaction effect, $F(2, 34) = 1.04$. Table 4 presents the univariate means on each of the certainty measures. Although the univariate analysis of variance of the difference ratio measure revealed no significant effects, the univariate analysis of the symmetry measure revealed a main effect of the information factor, $F(1, 35) = 7.01$, $p < .02$, no main effect of experiment ($F < 1$), and no interaction effect, $F(1, 35) = 1.99$, $p > .15$.

Although the two certainty measures appear to be reasonable, numerous other plausible measures can probably also be derived. Nevertheless, the present measures and the above multivariate analysis do provide some evidence that subjects in the no information condition may have been less certain of their judgments than were the partial information subjects.

Partner Selection

Table 5 presents the mean ratings of the extent to which each of the supposed others

[7] These two components were derived from the notion that the experimental task of indicating a best estimate and minimum and maximum estimates can be approached in two very different manners. A subject may make his or her best estimate of the distance the light moves and then decide upon a minimum and a maximum, in effect placing a confidence band around his or her best estimate (e.g., "I think it moved 3 inches, but it could be anywhere from 1 to 5 inches"). If this approach were taken, then the difference between the minimum and maximum estimates can be considered to reflect a confidence interval. Since the magnitude of the difference between maximum and minimum estimates is dependent upon the distance perceived, the ratio of the difference to the best estimate of the distance the light moved was computed. The mean ratio across the three trials of Series 1 forms the first component.

The task may have been approached in another manner, however. A subject may first establish a minimum and maximum and then set his or her best estimate somewhere within this range. If this approach were taken, the difference between maximum and minimum estimates could not be considered to reflect a confidence interval. With this approach, the logical recourse when one is not sure where within the range to locate the best estimate is to simply average the minimum and maximum estimates (e.g., "Let's see, it moved a minimum of 1 inch and a maximum of 5 inches. I'll say it moved 3 inches"). Thus, a subject might be said to be uncertain of his or her response if he/she simply chooses as the best estimate the average of the earlier established minimum and maximum distances, that is, if he/she simply sets a judgment symmetrically between the minimum and maximum. This appproach is reflected in the second component that was computed.

was desired as a partner. A 2 (No vs. Partial Information) × 2 (Similar vs. Dissimilar) × 2 (Agreer vs. Disagreer) analysis of variance, with the last two factors as repeated measures, revealed a main effect of each of the two within variables. In general, similar others ($M = 6.07$) were preferred over dissimilar others ($M = 5.27$), $F(1, 20) = 5.37$, $p < .05$, and the agreers ($M = 7.27$) were preferred over disagreers ($M = 4.07$), $F(1, 20) = 20.54$, $p < .001$. Each of these within-subjects factors interacted with perceived level of information. The general preference for a similar other over a dissimilar other was apparent in the no information condition (similar $M = 6.59$, dissimilar $M = 4.77$) but not in the partial information condition (similar $M = 5.55$, dissimilar $M = 4.77$), $F(1, 20) = 8.88$, $p < .01$. Correspondingly, the preference for an agreer over a disagreer was stronger in the partial information condition (agreer $M = 8.18$, disagreer $M = 3.14$) than in the no information condition (agreer $M = 6.36$, disagreer $M = 5.00$), $F(1, 20) = 8.76$, $p < .01$. However, the three-way interaction, which was to be expected if no information subjects had been concerned solely with construction and partial information subjects solely with validation, did not occur, $F < 1$.

Some confirmation of the hypotheses is provided by a priori t ratio comparisons of the no vs. partial information means. These comparisons rely on the notion that despite any concerns extraneous to informational social comparison that may have arisen in the experimental situation, the no information and partial information subjects should have divergent concerns with construction versus validation and hence should display differential preferences for the similar disagreer and the dissimilar agreer. As predicted, no information subjects expressed a greater preference for the similar disagreer than did partial information subjects, $t(20) = 3.57$, $p < .005$, and partial information subjects preferred the dissimilar agreer significantly more than did no information subjects, $t(20) = 3.23$, $p < .005$. The two conditions did not differ in their ratings of the similar agreer, $t(20) = 1.08$, or the dissimilar disagreer, $t(20) < 1$.

Inspection of Table 5 reveals that the data were not as was to be expected if subjects had been concerned only with informational social comparison. In each condition, the comparison other who was predicted to be most preferred, given that preferences were to be dictated only by informational motives, was not in fact most highly preferred. Although no information subjects did significantly ($p < .05$, by a least significant difference test) prefer the similar disagreer to the dissimilar disagreer, their ratings of the similar disagreer and the dissimilar agreer did not differ, and they tended ($p < .20$), if anything, to prefer the similar agreer to the similar disagreer. Partial information subjects did significantly prefer the dissimilar agreer to both the similar disagreer and the dissimilar disagreer, but they displayed equal preference for the two agreers. Thus, although the data were supportive in the sense that they suggest that desires to compare with a similar disagreer and desires to compare with a dissimilar agreer each vary as a function of perceived level of information, the similar disagreer was not the most preferred partner among the no information subjects, and the dissimilar agreer was not the most preferred other among the partial information subjects.

Table 5
Mean Partner Ratings in Experiment 3

Perceived level of information	Similar		Dissimilar	
	Agreer	Disagreer	Agreer	Disagreer
No	7.27 (6)	5.91 (3)	5.46 (1)	4.09 (1)
Partial	8.18 (7)	2.91 (0)	8.18 (4)	3.36 (0)

Note. The higher the mean, the more that person was preferred as a partner. Numbers in parentheses are the number of subjects who chose that person as a partner on the forced-choice measure.

The forced-choice data are also presented in Table 5. The data display the same general pattern as the ratings data. However, none of the No versus Partial Information comparisons are statistically significant, largely because of the overwhelming preference

among both groups of subjects for the similar agreer.

Motive for comparison. A 2 (No vs. Partial Information) × 2 (Construction vs. Validation) analysis of variance, with the last factor as a repeated measure, was performed on the ratings of desire for construction and validation. As in Experiment 1, the predicted interaction achieved statistical significance, $F(1, 20) = 4.93$, $p < .05$. In the no information condition, the construction and validation means were 7.64 and 5.27, respectively; in the partial information condition, these means were 7.00 and 8.09, respectively. Within-condition comparisons of construction means to validation means did not reach statistical significance.

Discussion

The value of similar disagreers versus dissimilar agreers appears to depend upon one's perceived level information. While these two sources are each potentially meaningful from an attributional perspective, they differ in the degree to which they appeal to an individual interested in construction vs. validation. As perceived level of information increases (and, correspondingly, as interest in construction tends to decrease and interest in validation tends to increase), preference for a similar disagreer decreases and preference for a dissimilar agreer increases. The similar disagreer is relatively more appealing to the person interested in construction than to the person interested in validation. If one is in a hypothesis-generating stage, it appears to be important to discover why a similar other, who should be agreeing, actually disagrees. The dissimilar agreer, on the other hand, is preferred relatively more by a person interested in validation than by a person interested in construction. Possessing what she/he believes to be a sufficient level of information, the person interested in validation may find the dissimilar agreer a useful comparison other. His or her agreement can only be attributed to their common sharing of the "facts" and informs the individual that his or her own judgment is not based upon some personal idiosyncrasy.

The difference in preference for a dissimilar agreer that was observed between no and partial information conditions in Experiment 3 also serves to clarify an interpretational difficulty encountered with respect to the data in Experiment 1. As pointed out earlier, selection of the agreer as a partner in Experiment 1 could have been motivated by many factors —only one of which is validation. For example, the relatively stronger preference for an agreer in the partial information conditions could have been due to self-esteem motives. This same difficulty is not encountered with respect to Experiment 3 because of the addition of the similarity manipulation. A dissimilar agreer appears to be the relevant choice for determining whether one's judgment is accurate. The fact that this person is more preferred by partial than by no information subjects provides evidence of an increased concern for validation in the partial as opposed to the no information conditions. The similar agreer would appear to be the relevant partner choice if one were concerned with self-esteem maintenance or enhancement. Since the two conditions did not differ with respect to their preferences for the similar agreer, it appears that self-esteem motives do not vary as a function of perceived level of information.

It should be recalled that the subjects in Experiment 3 did not display absolute preferences for the predicted comparison other. That is, no information subjects did not most strongly prefer the similar disagreer. Nor did partial information subjects most strongly prefer the dissimilar agreer. These absolute preferences were to be expected to the extent that partner choice was dictated solely by informational concerns. Apparently, the experimental situation was not successful in creating such "pure" motives. Whether "pure" motives and absolute preferences occur in any given situation is likely to depend upon a number of additional parameters. In particular, it is likely to depend upon the importance of the task to the individual (cf. Jones & Regan, 1974). There are many reasons to choose a specific other as a partner. The less important the given task and informational social comparison reasons are in a

given situation, the more likely it is that these other factors will affect absolute preferences. In the present case, the noncritical nature of the experimental task and the anticipated ease of discussing a judgment with a similar agreer clearly affected absolute preferences. Only when the data are considered in relative terms are informational social comparison motives and their dependence upon perceived level of information apparent.

Why, when the data are considered in absolute terms, did so many subjects in each of the conditions prefer to have the similar agreer as a partner? One possibility is that subjects who chose the similar agreer may have done so because the task threatened their self-esteem. That is, rather than being primarily concerned with informational social comparison, these subjects may have been largely concerned with their self-esteem. A further analysis of the data provides some interesting insight. An internal analysis was performed in order to examine whether subjects who chose the similar agreer felt more uncertain of their judgments than did subjects who made the predicted partner choice. The discriminant weights from the multivariate analysis of variance on the difference ratio and symmetry measures of certainty were employed in order to construct a weighted sum that could serve as an index of certainty. Within the no information condition, those who chose the similar agreer tended to be less certain of their judgments than those who chose the similar disagreer ($p < .10$, by a two-tailed Mann–Whitney test). Among the partial information subjects, a similar pattern was evident. Those who chose the similar agreer tended to be less certain than those who selected the dissimilar agreer ($p < .10$). Collapsed across the two conditions, there was a significant difference between the subjects who chose the similar agreer and those who chose either the similar disagreer or the dissimilar agreer ($p < .01$). The results of this internal analysis suggest that an individual will not engage in either process of informational social comparison if he/she is very uncertain of his or her judgment. Rather than reveal the context of his or her uncertainty, the individual may simply ignore the need for informational social comparison. Concerns with self-esteem maintenance may become primary. The similar agreer is likely to have been perceived as the least threatening potential partner. Discussion with someone who is similar in perceptual style and who has agreed on past trials may have been viewed as a relatively safe and easy alternative. In addition, such comparison may provide a sufficient bolstering of one's certainty that one may subsequently be willing to test one's judgment in a more objective manner via informational social comparison.

Although the above internal analysis is quite revealing, the finding is a bit troubling in that it runs counter to the basic premise that informational social comparison is to be expected under conditions of uncertainty. Apparently, extreme uncertainty leads, not to a desire for information, but a feeling of threat and a desire to protect one's self-esteem. (See Conolley, Gerard, & Kline, 1978, for a similar discussion of the relation between uncertainty and informational vs. self-esteem motives within the context of ability comparison.) The current findings suggest that once a threshold of certainty is achieved such that the individual no longer feels threatened, the person is willing to "risk" informational social comparison. Whether construction or validation processes then occur will depend upon the person's level of uncertainty.

Future research will need to address the issue of informational versus self-esteem comparison further. Presumably, however, concerns for self-esteem among individuals who feel extremely uncertain would be overridden in situations where the individuals are making important and consequential decisions and need information to do so. That is, the threshold certainty level that must be achieved for a person to "risk" informational social comparison may vary as a function of the importance of the judgment in question. Furthermore, in such important situations, one of the comparison others whose value tends to vary as a function of perceived level of information (i.e., the similar disagreer or the dissimilar agreer) may become the most strongly preferred comparison other. That is, the relative effects observed in Experiment 3

when no and partial information conditions were compared may also become evident in absolute terms when important judgments are being made.

The Social Learning Theory of Sex Differences: Imitation is Alive and Well

David G. Perry
University of Alberta, Edmonton, Canada

Kay Bussey
Stanford University

The hypothesis that sex role development depends in part upon children's tendencies to imitate same-sex individuals more than opposite-sex models is central to most theories of sex typing. Yet Maccoby and Jacklin, in an influential recent review of the literature, conclude that the hypothesis has been disconfirmed. In the present article, it is argued that the research on which Maccoby and Jacklin based their conclusion is weak both methodologically and conceptually. This article presents a modified social learning theory account of the contribution of imitation to sex role development. It is suggested that children learn which behaviors are appropriate to each sex by observing differences in the frequencies with which male and female models as groups perform various responses in given situations. Furthermore, children employ these abstractions of what constitutes male-appropriate and female-appropriate behavior as models for their imitative performance. A first experiment confirmed that children engage in these processes. A second experiment extended the validity of the formulation by showing how it accounts for children's imitation of individual adult models. Specifically, it was shown that a child's imitation of an adult is strongly influenced by the degree to which the child believes that the adult usually displays behaviors that are appropriate to the child's sex (that is, behaviors that occur with greater frequency among individuals of the child's sex than among opposite-sex persons). In sum, the present research reinstates same-sex imitation as a viable mechanism of sex role development.

Sex role development, or sex typing, is the process by which children come to adopt the attitudes, feelings, behaviors, and motives that are culturally defined as appropriate [1] for their sex (Hetherington, 1967; Mischel, 1970). Virtually every leading theory of sex typing assigns a prominent place to imitation in the process. Psychoanalytic theory (Freud, 1949), cognitive-developmental theory (Kohlberg, 1969), cognitive consistency theory (Kagan, 1964), and social learning theory (Bandura & Walters, 1963; Mischel, 1966, 1970) all suggest that psychological differences between the sexes are at least in part perpetuated by the fact that boys and girls as groups are more inclined to imitate responses displayed by same-sex models than they are to imitate opposite-sex models. Furthermore, within each sex, individual differ-

This research was supported by an Australian Research Grant to the first author and an Australian Commonwealth Postgraduate Scholarship to the second author. [1] The question of whether a given response is more "appropriate" to one or the other sex can be determined in any of a number of ways. These include consensus by a panel of judges, empirical determination of the relative frequency with which the response is performed by the two sexes, and differences in the consequences boys and girls receive for performing a given response. Regardless of the manner in which one chooses to operationalize sex-appropriateness of behavior, however, the processes through which sex role learning is effected are likely to be similar, and it is with process that the present article is concerned.

ences in children's masculinity and femininity (or the degree to which a child displays responses appropriate, respectively, to the male or female sex) are believed to stem in part from the strength of children's tendencies to prefer imitation of one sex model over the other.

Recently, the validity of the hypothesis that psychological differences between the sexes are due in any significant degree to differential imitation of same-sex models has come under serious attack, notably by Maccoby and Jacklin (1974). These authors argue forcefully in their influential volume that the research to date fails to support the idea that differential imitation of like-sex models is probably a mechanism through which sex differences eventuate.

In arriving at their conclusion, Maccoby and Jacklin (1974) reviewed more than 20 imitation studies in which both sex of subject and sex of model had been included as factors in the research design, and they discovered that the vast majority of such studies failed to find a significant interaction of sex of observer and sex of model on children's imitation. A more recent review (Barkley, Ullman, Otto, & Brecht, 1977) included more than 80 studies and reached essentially the same conclusion. Furthermore, the same null result holds regardless of whether the modeled behavior is traditionally sex-typed or not and of whether the models are strange adults or familiar persons such as the child's own parents. Maccoby and Jacklin therefore concluded that it is necessary to search for factors other than same-sex imitation (e.g., biological determinants or direct elicitation and reinforcement of sex-appropriate behavior) to account for sex typing. If accepted, the Maccoby and Jacklin conclusion would constitute a devastating blow to most psychologists' understanding of the sex-typing process since, as has been pointed out, most theories assign a prominent role to the imitation of same-sex models.

We believe that it is premature to abandon the same-sex imitation hypothesis altogether. The results of these literature reviews suggest, however, that if the same-sex imitation hypothesis is to be retained, then a reconceptualization of the way in which same-sex imitation contributes to sex role development may be in order.

It is our contention that the typical investigation designed to explore same-sex imitation has employed an experimental paradigm that is conceptually remote from how imitation actually contributes to sex role development and therefore that the null results of much of the previous research on same-sex imitation constitute an inappropriate base for rejecting the same-sex imitation hypothesis. In the typical investigation, children are exposed to a single (often unfamiliar) male and/or female performing (often novel) responses and are then tested for imitation of the models' responses. The same-sex imitation hypothesis, in its usual form, predicts that children will view the actions of the single same-sex model as a better guide for their own behavior than the actions of the opposite-sex model and will thus imitate the former model more. This is actually quite unlike the way in which children use the responses of same- and cross-sex models as guides to their own behavior in naturalistic settings. In the real course of development, children discern what behaviors are appropriate for each sex by watching the behavior of *many* male and female models and by noticing differences between the sexes in the frequency with which certain behaviors are performed in certain situations. They then use these abstractions of sex-appropriate behavior as "models" for their own imitative performance. This is quite a different view from assuming that children develop such widely generalized tendencies to imitate same-sex models that they readily take the behavior of a single same-sex model as a more reliable guide to their own behavior than the behavior of an opposite-sex model, even when the same-sex model is unfamiliar or displays novel responses, or when the child has no idea about whether the model's behavior is likely to be consensually validated by others of the model's sex.

When conceptualizing the contribution of imitation to sex-role development, we find it useful to draw on the distinction made by social learning theorists between the observational learning and performance of modeled

behavior (Bandura, 1965, 1977; Mischel, 1970). According to social learning theory, through the observation of the behavior of models of both sexes, children cognitively acquire the potential to perform a vast repertoire of social behaviors that includes not only behaviors appropriate to the child's own sex but also (at least most of) the behaviors appropriate to the opposite sex. This is accomplished through such observational learning strategies as attending to the models' actions, coding the models' responses into covert imaginal or symbolic representations, and mentally rehearsing the models' actions. We propose that an additional and crucial (for sex typing) aspect of the observational learning process involves children's coding, or organizing in memory, of various responses as male-appropriate or female-appropriate on the basis of their having witnessed different proportions of available male and female models performing the responses. For example, if children observe that 80% of available male models perform a particular response in a given situation but only 5% of female models perform it, they are likely to code the response as male-appropriate or masculine.

Not everything learned is performed, however. Thus, although most boys know how to put on a dress, apply makeup, and primp in front of a mirror, few boys actually choose to perform these behaviors. Children are most likely to perform behaviors they have coded as appropriate for their own sex. According to social learning theory, which responses children select to perform from their repertoires depends primarily on the response consequences the children anticipate. Children should prefer to perform behaviors exhibited by same-sex models, because they have more often been rewarded and less often criticized for imitating same-sex models and because they gradually learn that the social environment holds similar expectations and imposes similar reinforcement contingencies on them and others of their sex (Bandura, 1969; Bussey & Perry, 1976; Mischel, 1970). In sum, although children acquire, via observational learning, behaviors that are appropriate to both sexes and label certain responses as same-sex-appropriate and others as opposite-sex-appropriate, they prefer spontaneously to imitate actions coded as same-sex-appropriate. This is because they infer that what is expected or permissible behavior for others of their sex is also likely to be appropriate behavior for them.

Our first experiment constitutes a laboratory analog study of how we hypothesize same-sex imitation to operate in naturalistic settings. In real life, male and female models as groups frequently diverge in the responses they display in a given situation. When confronted with a similar situation and the option to perform one of the responses they have seen male and female models exhibit, children should be inclined to choose an option they recognize as same-sex appropriate. Consider, for example, a 10-year-old boy who has recently transferred to a new school. In his first days, he observes that during recess the majority of girls play hopscotch, whereas most of the boys play baseball; that during library periods, most boys check out a Hardy Boys mystery, whereas most of the girls read Nancy Drew; that when given a choice of technical electives, boys choose woodwork, whereas girls choose sewing. Even if the boy has not previously observed sex differences in the performance of these various responses, he is now likely to code the responses as masculine or feminine and to use these codings as guides to his own response selection. Experiment 1 was designed to determine whether these suggestions are tenable.

Experiment 1

Method

Overview. Boys and girls were assigned to one of three modeling conditions or to a no-model control condition. In all the modeling conditions, children viewed 8 adult models (4 male, 4 female) individually and indicated their preferences on a series of two-choice preference tasks. In a first experimental condition, on every trial all the male models chose one of the items and all of the women chose the other item. In a second condition, on every trial 3 of the men and 1 of the women chose one item and the remaining man and women chose the other item. In a third condition, on every trial 2 of the men and 2 of the women chose one item and the other 2 men and 2 women chose the other item. Subjects in the no-

model condition skipped this phase. Subsequently, children in all groups were asked to indicate their own preferences for each item pair. The hypothesis was that children's endorsement of an item would be a function of the difference in the frequency with which same- and opposite-sex models had displayed a similar preference—the greater the difference, the more likely same-sex imitation was hypothesized to be.

Participants. Subjects were 96 8- and 9-year-old children, half boys and half girls, who attended a public school in a middle-class suburb of Brisbane, Australia. Models were four men and four women, all in their twenties. The experimenter was a female in her early twenties.

Stimuli. The preference task involved 16 pairs of objects. Within each pair the items belonged to the same class (e.g., a banana and an apple; a small plastic cow and a small plastic horse). Models were shown (on a black and white video monitor) making their choices from among the actual items, which were presented to them by an adult female (not the experimenter). The preference task was presented to subjects by showing them 16 color slides, each depicting one item pair. We deliberately selected responses as modeling stimuli that did not have clearly established histories of being more appropriate for one sex than the other. This was because our major goal was to demonstrate in the laboratory a major process through which previously sex-neutral responses *become* sex-linked. Furthermore, the use of already sex-typed responses could introduce potentially troublesome and irrelevant factors (e.g., the relative interest value of masculine and feminine behaviors) that might render unambiguous interpretations of the results in terms of cause and effect relations quite difficult.

Procedure. Each child was brought individually by the experimenter to a spare room on the school premises and, if assigned to a modeling condition, was seated before the video monitor. To modeling subjects, the experimenter explained that they would watch some people telling which things they "like better." In all modeling groups, the children saw, on the video monitor, the experimenter place the first item pair on a table before the eight models, individually solicit a preference from each model, and then continue to the next item pair until all 16 trials were completed. The models, who were asked for their preferences in a different order on every trial, always indicated their preference by pointing to the item of their choice and saying, "I like the (item) better." On each trial, four models always chose one item and the other four the remaining item. This equated for all groups the number of models endorsing a given item. Twelve boys and 12 girls were randomly assigned to each of three modeling conditions or to a no-model control condition which were run concurrently in a randomized blocks procedure.

In the first modeling condition, or *high (100%) within-sex consensus* modeling condition, for every item pair all the men chose one item and all the women chose the other item. Two modeling tapes were made for this condition, with half the subjects seeing one tape and the remainder seeing the other. The tapes were designed to counterbalance for the sex of model displaying a given item preference. For the first tape, determination of whether the men or the women chose a given item was determined randomly for each trial. On the second tape, the sex of the models choosing a given item was opposite to the sex of the models who had chosen that item on the first tape.

In the second modeling condition, or *moderate (75%) within-sex consensus* modeling condition, on every trial three men and one woman chose one item and the remaining three women and one man chose the other item. The identity of the man who chose as did the majority of the women and of the woman who chose as did the majority of the men changed from trial to trial, with each model serving four times as the "odd person out" for his or her sex. Half of the subjects watched a tape in which the items preferred by the three male models were identical to those preferred by all the men in the first tape used in the high within-sex consensus condition; the remaining subjects saw a tape in which the items preferred by the three male models were those that had been preferred by all the men in the second tape used in the high within-sex consensus condition.

In the third modeling condition, or *low (50%) within-sex consensus* modeling condition, on each trial two of the men and two of the women chose one item, whereas the remaining models chose the other item. Again, two tapes were used, with half the subjects viewing each. In the first tape, two men and two women were randomly drawn, for each trial, to make the same item choices as those made by all the men for that trial on the first tape used in the high within-sex consensus condition. The remaining models chose the other item. In the second tape, the two men and the two women who had been drawn for a given trial made the choice for that trial that had been made by all the male models in the second tape of the high within-sex consensus condition.

The remaining 12 boys and 12 girls were assigned to a no-model condition and proceeded directly to the imitation test after arrival at the experimental room. Children in the modeling groups proceeded to the imitation test immediately after the models had made their choices for the 16th item pair and the video equipment had been shut off.

In the *test for imitative performance,* children were shown the 16 slides depicting the item pairs and were told to indicate for each slide (verbally as well as by using a pointer) which item they preferred.

Subjects in the three modeling conditions were then given a *recall test.* The experimenter once again displayed the 16 slides, pointed to one of the two items for each slide, and instructed the child to tell if more of the men had liked that item, if more of the women had liked it, or if an equal number of men

and women had liked it. Children were promised a token (exchangeable for small prizes) for each correct answer.

Children in all groups were told they had performed very well and were awarded little prizes that were distributed when testing was completed.

Results

Imitative performance. An imitation score was derived for every child in the study by counting the number of the child's choices that matched the choices that had been unanimously *displayed by the male models in the high within-sex consensus modeling condition.* These scores of course could vary from 0 to 16 for a given child. The reasoning behind choosing imitation of the responses displayed by the male models in the high within-sex consensus condition as the datum to be compared across treatments is the following. According to the hypothesis of the research, boys' imitation of these responses should be highest in the high within-sex consensus condition and girls' imitation should be lowest in this condition. This follows from the prediction that children's endorsement of an item will be a function of the percentage of same-sex models who had displayed the preference. In this condition, 100% of the male and 0% of the female models endorsed these items. To see how changes in the percentage of same- and opposite-sex models endorsing an item alter imitation, it is necessary to examine imitation of the *same responses* but under conditions where the percentages of same- and opposite-sex models endorsing them have changed. This is most easily done by maintaining imitation of the male models' responses from the high within-sex consensus condition as the dependent variable across treatment conditions. As we move from examining children's imitation of these responses in the high within-sex consensus condition to the moderate and then the low within-sex consensus conditions, boys' scores should steadily decrease, and girls' should steadily increase. This is because the percentage of male models endorsing the preferences exhibited by the male models in the high within-sex consensus condition decreases as one moves to the moderate and then the low conditions, whereas the percentage of female models endorsing these responses increases as we move in this direction.

Recall that within each of the three modeling conditions, two modeling tapes were used (in order to counterbalance the models' choices), with half the children in each condition viewing one tape and the other half seeing the other tape. This affected computation of children's imitation scores in two ways. First, imitation scores for subjects in each modeling condition who viewed the first modeling tape for their condition (described in the method section) were computed by counting the number of the children's choices that matched the choices unanimously made by the male models in the first modeling tape of the high within-sex consensus modeling condition; imitation scores for subjects in each condition who viewed the second tape for their condition were computed by counting the children's choices that matched the choices unanimously made by the male models in the second modeling tape of the high within-sex consensus modeling condition. Second, imitation scores for subjects in the no-model group were calculated as follows: For a random half of the subjects, scores were taken as the number of choices that matched those of the male in the first modeling tape of the high within-sex consensus modeling condition; for the remaining no-model subjects, scores were taken as the number of choices that matched those of the male models in the second modeling tape of the high within-sex consensus modeling condition.

The mean imitation scores are presented separately for boys and girls for each treatment condition in Table 1. It may be seen that the data lend strong support to the hypothesis that children's imitation of a response increases as the percentage of same-sex models displaying the response increases. It is interesting to note that essentially identical results were achieved for girls. The fact that girls imitated, on the average, only 2.8 of the males' responses in the high within-sex consensus condition of course means that they were imitating 13.2 of the choices that 100% of the female models had made. As the percentage of female models endorsing these re-

Table 1
Imitative Performance Means of Boys and Girls in Each Treatment Condition (Experiment 1)

Child	Treatment condition			
	High (100%) within-sex consensus	Moderate (75%) within-sex consensus	Low (50%) within-sex consensus	No-model control
Boys	13.9_e	11.6_d	8.7_c	8.5_c
Girls	2.8_a	5.8_b	8.5_c	8.2_c

Note. For all treatment conditions, a subject's imitation score was the number of his or her preferences that matched those made by the male models in the high within-sex consensus condition. A subject's score could range from 0 to 16. Each mean is based on scores of 12 subjects. Cells not sharing a common subscript differ significantly from each other ($p < .05$) by a two-tailed t test.

sponses declined, so too did the girls' imitation of them. It can be seen, then, that the imitative performance of both boys and girls is strongly affected by changes in the frequency with which same- and opposite-sex models display the behavior.

An analysis of variance was performed on the means in Table 1, with sex of child and treatment condition as factors. There was a strong main effect of sex of child, $F(1, 88) = 162.87$, $p < .001$, as well as a significant interaction of sex of child and treatment condition, $F(3, 88) = 58.50$, $p < .001$. The sex main effect is, of course, due to the fact that imitation scores were determined by children's imitation of preferences given by the male models in the high within-sex consensus condition. If imitation of the preferences given by the female models in this condition had arbitrarily been chosen as the dependent variable, then of course a highly significant main effect of sex in the opposite direction would have been obtained. The significant interaction effect and its pattern clearly substantiate the conclusions reached above.

A final comment on the performance results is in order. When children skipped the modeling phase and therefore had no information about the sex-appropriateness of the responses, their imitation of the responses was not markedly different from when they observed equal numbers of male and female models display them (as in the low within-sex consensus condition). In fact, within each of the two rows of Table 1, all pairwise comparisons between means are significant (by two-tailed t tests) at $p < .05$, except for the comparison between the mean of the low within-sex condition and that of the no-model control condition.

Recall. Children in each modeling condition were asked, for each item choice displayed by the male models in the high within-sex consensus condition, whether more of the men, more of the women, or equal numbers of men and women had chosen it. The number of correct answers the children gave were analyzed in a 2×3 analysis of variance with sex of subject and modeling treatment condition as factors. The only significant effect was the main effect of treatment condition, $F(2, 66) = 7.78$, $p < .002$. Mean correct responses for the high, moderate, and low within-sex consensus conditions, respectively, were 14.4, 12.6, and 11.9. Clearly, the more consensus in choices there is among models of a given sex, the better able children are to remember whether and how the behavior is sex-typed. Boys and girls do not seem to differ in their propensities to do this.

Discussion

The research clearly supports our revised version of the same-sex imitation hypothesis. It is quite clear that when children observe same-sex models as a group exhibiting a response that diverges from the response made collectively by opposite-sex models under the same circumstances, the children are far more likely to imitate the response made by same-sex models. Obviously, the research restores same-sex imitation as a plausible mechanism of sex role development and reverses the Mac-

coby and Jacklin (1974) decision. However, the study suggests that the same-sex model for a child's imitation is the child's abstracted definition of appropriate behavior for the child's sex based on the child's observation of multiple examples of each sex behaving in a particular situation.

Experiment 2

Previous research on the same-sex imitation hypothesis has been guided by the assumption that children develop strongly generalized tendencies to imitate same-sex models. Recent reformulations of social learning theory (Bandura, 1977; Bandura & Barab, 1971; Mischel, 1968, 1973), however, stress the discriminating nature of children's selection of responses and models from among the vast array available to them. The negative results of research on the same-sex imitation hypothesis suggest that children do not automatically assume that a strange same-sex adult is a more appropriate role model for them than an opposite-sex model. Children probably learn quite early that individual differences exist among male and female models in terms of their masculinity and femininity and thus their suitability as models. Children should imitate a model when they believe the model's behavior is appropriate for them, too, but in order to conclude that a same-sex model is an especially reliable guide for their own behavior, the children must have some fairly unambiguous indication that the model is behaving typically for his or her sex (and is therefore an appropriate model). Experiment 2 tested this possibility.

Method

Overview. In an initial phase, children observed 8 adult models, 4 male and 4 female, indicating their preferences on a series of two-choice preference tasks. On each trial, 3 of the men and 1 woman chose one item, whereas the other man and the remaining women chose the other item. Across the trials, it was always the same man who chose as the 3 women did, and it was always the same woman who chose as the 3 men did. Thus, it was expected that over the trials children would learn that 3 of the men consistently concurred in their choices and thus were behaving sex-appropriately, whereas 1 of the men consistently chose with the majority of the women and thus was behaving sex-inappropriately. Similarly, children were expected to learn that the behavior of 3 of the women was sex-appropriate but that that of the fourth was sex-inappropriate. Some children (assigned to a no-premodeling control group) skipped this first phase and proceeded straight to the second phase.

In a second phase, children viewed 1 of the 8 models making choices alone on a new series of preference trials. For half of the children who had participated in the first phase, this model was one of those who had behaved appropriately for his or her sex during the first phase; for the other half of the children who had participated in the first phase, the model was one who had behaved sex-inappropriately in the first phase. Children who skipped the first phase (no-premodeling control subjects) also saw one of the models from the first phase, but of course they had no idea of the degree to which the model's behavior had previously agreed or disagreed with that of other members of his or her sex. Half of the children in each of these three groups saw a male model and the other half a female model.

In a third phase, children were tested for imitation of the preferences the single model had displayed in the second phase. It was predicted, first, that same-sex imitation effects would not occur for children assigned to the no-premodeling control group because these children (as in most previous studies) would not know whether the model was behaving appropriately or inappropriately for his or her sex. Second, it was predicted that same-sex imitation effects would be extremely powerful among children exposed to a same-sex model whose behavior the children knew had a history of concurrence with other same-sex models.

Participants and design. Subjects were 84 8-year-olds, half boys and half girls, enrolled at a school in a middle-class suburb of Brisbane. Six boys and six girls were assigned to cells in a 2 × 3 × 2 design involving Sex of Child × Sex-Appropriateness of the Single Model Seen in Phase 2 (appropriate, inappropriate, or no-premodeling control) × Sex of Model. An additional six boys and six girls were assigned to a no-model control condition. These children skipped the first two phases (that is, both modeling phases) but were asked for their own preferences during the third phase just as the other children were. Children had an equal chance of being assigned to any of the experimental design groups or to the no-model group, which were run concurrently in a randomized blocks procedure. The models and the female experimenter were the same as in the first experiment.

Stimuli. Stimuli used to solicit models' preferences during the first, multiple-modeling phase were different from but similar to those used in the first experiment. Again, there were 16 item pairs. The same set of 16 item pairs was used during the second, single-modeling phase as had been used in Experiment 1. Models in both phases were shown making choices from the actual items on a black-and-white video monitor. Children were asked for

their own preferences in the third phase and were shown the 16 color slides used in Experiment 1.

Procedure. Subjects were tested individually in a spare room at the school. Subjects participating in the first phase (multiple modeling) viewed the eight models making their choices, as in Experiment 1, on the video monitor. Three of the men always chose one item and three of the women always chose the other item; the remaining man and woman (inappropriate models) always chose as the majority of the opposite-sex models did. It should be clear that this treatment was identical to that received by subjects in the moderate within-sex consensus condition of Experiment 1, with the exception that in the present experiment the identity of the odd model out for his or her sex remained constant across trials. No-premodeling control children and no-model control children skipped this phase.

Children who had participated in the first phase or who were assigned to the no-premodeling control group participated in a second phase (single modeling). Children saw one of the male or one of the female models from the multiple modeling video tape indicate his or her preferences on a series of 16 new item choices. This modeling sequence was also presented on videotape. For children who had participated in the first, multiple-modeling phase, this model was one whom they had previously seen behave either appropriately or inappropriately for his or her sex. Children in the no-premodeling control condition observed one of the same models that children who had participated in the multiple-modeling phase saw, but as noted, they had no basis for knowing whether the model had a history of behaving appropriately or inappropriately for his or her sex.

To minimize contamination of the results by idiosyncratic attributes of the particular model that children viewed during this second, single-modeling phase, different models served as appropriate and inappropriate models for different groups of children. To have given each of the eight models a chance at participating in each of the various roles he or she could have assumed would have necessitated making a prohibitively large number of modeling tapes. As a compromise, the following procedure was used. Two multiple-modeling tapes were made for use in the first phase. Half the subjects participating in this phase saw one tape and the other half saw the other tape. For each of the two tapes, a different male or female model served as the model who made inappropriate choices for his or her sex. Children who were assigned to see an inappropriate model in the second phase of course viewed whichever model had served as the inappropriate model in the tape they had seen in the first phase (with half seeing the male and half seeing the female model). Children who were assigned to see an appropriate model in the second phase, however, viewed whichever model had served as the inappropriate model in the tape they had *not* seen (but who, of course, had served as one of the three appropriate models in the tape they *had* seen). For children assigned to the no-premodeling control condition, half viewed one of the two male models who had served as either an appropriate or an inappropriate model for children in the other conditions, and the other half viewed one of the two female models who had served in one of these roles for the other children. These procedures equated the frequency across conditions with which children viewed a particular model in the second phase as well as permitted more than one of the male and one of the female models to play the sex-inappropriate role.

In this study all the models made the same choices in the second phase. Extra tapes depicting the models making opposite choices were not used because examination of the data from Experiment 1 indicated that similar results were obtained regardless of the models' actual choices. The model's choices in the present experiment were the same as the choices seen by the children who saw the first tape in the high within-sex consensus modeling condition of the last experiment.

All children, including those assigned to a no-model control condition, were then shown the 16 slides depicting the item pairs used in the second phase and were told to give their own preferences, as in Experiment 1.

Children in the modeling conditions were asked to recall the choices the model had made in the second phase and were promised rewards for doing so. Finally, children were asked to respond on 7-point scales to the questions, "How much do you like (the model)?", "How much are you like (the model)?" "Do you think that most people would like (the model)?", and "How good is (the model) at making choices?" Children received small prizes for participating and were returned to the classroom.

Results

Imitative performance. A $2 \times 3 \times 2$ analysis of variance with sex of child, sex-appropriateness of the model, and sex of model as factors was performed on imitation scores of all the children except those assigned to the no-model control condition. Significant effects included sex of subject, $F(1, 60) = 9.32$, $p < .005$; sex-appropriateness of model, $F(2, 60) = 19.55$, $p < .001$; the interaction of sex of subject and sex of model, $F(1, 60) = 9.92$, $p < .005$; and sex of model with sex-appropriateness of model, $F(2, 60) = 3.27$, $p < .05$. However, the three-way interaction among all the variables was also highly reliable, $F(2, 60) = 41.15$, $p < .001$. The means for this analysis are given in Table 2. The least significant difference required for

Table 2
Imitative Performance Means for Interaction of Sex of Subject, Sex-Appropriateness of Model, and Sex of Model (Experiment 2)

Subject and model	Sex-appropriateness of model		
	Appropriate	Inappropriate	No-premodeling control
Boys			
Male model	14.7_{f}	4.3_{a}	13.2_{def}
Female model	3.5_{a}	9.3_{be}	12.0_{de}
Girls			
Male model	8.2_{b}	11.2_{cd}	12.7_{def}
Female model	14.3_{ef}	8.3_{b}	12.8_{def}

Note. Each mean is based on six subjects' scores. Cells not sharing the same subscript are significantly different from one another ($p < .05$) by a two-tailed t test.

any two means in this table to be reliably different from one another at $p < .05$ by a two-tailed t test is 2.62.

The results confirm the hypotheses. First, examine the data for children assigned to the no-premodeling control condition by glancing down the third column in Table 2. None of the means in the column is significantly different from any other mean in the column. This substantiates the prediction that when children do not know how the behavior of a model compares with that of other members of the model's sex, the same-sex imitation hypothesis is not confirmed. Also note that the means in this column are all relatively high. This suggests the possibility of a ceiling effect. When children see only one model displaying item preferences in an experimental setting and they do not know whether the model is a "good" or "bad" example for his or her sex, they may assume that the model—regardless of sex—is likely to be a relatively safe example to follow in that setting. That the high scores in the no-premodeling groups are in fact due to imitation is apparent from the fact that children assigned to the no-model control condition made choices that matched the models' at a substantially and significantly ($p < .05$) lower rate (M for boys in no-model group = 8.0; M for girls = 8.2).

The second hypothesis was that same-sex imitation effects would occur when the children were exposed to a model whose behavior, they had learned, was typical of others of the model's sex. It is evident, by glancing down the first column of Table 2, that this hypothesis received strong support, especially for boys. Note how boys who saw a sex-appropriate female model actually chose fewer of the model's responses than they did when they had not seen any model perform at all ($p < .05$).

Two other features of the pattern of means are noteworthy. First, glance down the middle column of means in Table 2, where data are presented for children's imitation of a model whom they had previously seen behave sex-inappropriately. Apparently, when children know an opposite-sex model is a more reliable indicator of behavior appropriate to the child's own sex than a same-sex model, they are more likely to imitate the opposite-sex model. Interestingly, cross-sex imitation is really evident only among girls, because the imitation scores displayed by girls exposed to an inappropriate male model ($M = 11.2$) were significantly ($p < .05$) higher than the imitation scores of no-model control girls ($M = 8.2$). In contrast, boys' imitation scores were not significantly higher with an inappropriate female ($M = 9.3$) than in the no-model control condition ($M = 8.0$). Boys may ignore rather than imitate females who behave masculinely.

A second point is that boys more actively inhibited imitation of sex-inappropriate behavior than girls. Imitation scores of boys who saw either an inappropriate male model ($M = 4.3$) or an appropriate female model ($M = 3.5$) were lower ($p < .05$ in each case) than those of no-model control boys. In con-

trast, girls did not inhibit imitation of male-appropriate behavior, when it was displayed by either a male ($M = 8.2$) or a female ($M = 8.3$) model.

Recall. Correctly recalled choices of the model were subjected to a similar $2 \times 3 \times 2$ analysis of variance. No effect attained significance (Grand $M = 15.1$).

Questionnaire data. Children's responses to the four postexperimental questions were subjected to similar three-way analyses of variance. No significant effects were obtained on the first question, which asked children to indicate their attraction to the model. For the second question, which asked children to rate their similarity to the model, several effects were significant, but they were all subsumed by a significant highest order interaction, $F(2, 60) = 14.03$, $p < .001$. The means indicated that when children saw a sex-appropriate model, there was stronger perceived similarity to a same-sex model for both boys and girls; when children saw a sex-inappropriate model, boys actually expressed greater similarity to the female model than the male model (no parallel result occurred for girls); among children in the no-premodeling conditions, there were no differences in perceived similarity to the model. It is, of course, important to remember that these data were collected after the subjects' imitation test and may thus have been influenced by their imitative performance. On the third question, which asked children to tell whether most people would like the model, there were no significant effects. On the final question, which asked children to indicate how good they thought the model was at making choices, there was a significant three-way interaction, $F(2, 60) = 3.97$, $p < .05$. It appeared that the only major contributor to this interaction was the fact that boys in the no-premodeling control condition perceived the female model as more competent than the male at making choices. Why this result emerged is unknown. However, in sum it appears that neither perceptions of the model's competence nor attraction to the model can account for the imitation results. On the other hand, perceived similarity to the model does appear as an influential possibility.

General Discussion

The major contribution of the present research is to reinstate same-sex imitation as a viable mechanism of sex role development. Maccoby and Jacklin's (1974) conclusion that differential imitation of same-sex models contributes negligibly to sex role development was based on the results of studies that lacked an adequately developed conceptual framework of how imitation contributes to the social learning of sex differences. The present article demonstrates quite clearly that children discern behaviors appropriate to the two sexes by observing differences between the sexes in the frequency with which they perform various responses in a given situation and, furthermore, that children use these abstractions concerning sex-appropriate behaviors as guides to their own performance in similar situations.

The research also demonstrates that a child's imitation of a single model is in part governed by the degree to which the child has come to believe that the model's behavior is ordinarily appropriate or inappropriate to the child's sex. In other words, children are most likely to imitate persons whom they perceive to be good examples of their sex role. It is of interest that some previous research has shown that girls are especially likely to imitate a warm or nurturant model, whereas boys are particularly likely to imitate a dominant model (Hetherington, 1967). This may be in part because children usually perceive warmth as indicative of femininity and dominance as reflective of masculinity (Best, Williams, Cloud, Davis, Robertson, Edwards, Giles, & Fowles, 1977; Rothbaum, 1977; Williams, Bennett, & Best, 1975). Clearly, then, children judge the likely appropriateness of an individual model's behavior by recalling how well that person's attitudes and behaviors usually match up with others of his or her sex.

According to social learning theory, children acquire (via observational learning) responses appropriate to both sexes but prefer to perform responses exhibited by same-sex models. In other words, model sex affects performance more than observational learning. Results of the second study are quite in

line with this proposition. In this experiment, there were no significant effects of the experimental variables upon children's recall of the model's behavior, although the same factors strongly affected children's imitative performance. These results mesh with those of Williams et al. (1975), who found that boys and girls do not differ in their knowledge of cultural stereotypes for male and female behavior which, we could argue, are primarily learned via observational learning. We do not wish to overstate the case, however. Several studies do show that children sometimes attend more closely to, as well as learn more about, the behavior of models consistent with their own sex role (Grusec & Brinker, 1972; Maccoby & Wilson, 1957; Maccoby, Wilson, & Burton, 1958; Perry & Perry, 1975; Slaby & Frey, 1975). Nadelman (1974) also found that children were able to identify correctly the sex-appropriateness of items appropriate for their own sex better than they were able to identify the sex-appropriateness of items traditionally associated with the opposite sex. Thus, although the preference for performing same-sex behaviors may well be stronger than the preference for learning same-sex behavior, it is not as though the latter phenomenon is nonexistent.

Our analysis of same-sex imitation in sex role development suggests that children must master certain cognitive achievements before their sex typing can to any significant degree be influenced by imitation of like-sex models. Before children will encode responses they see performed more often by members of a given sex as male- or female-appropriate, they must realize that human beings are divided into males and females. Before they will prefer to perform responses coded as same-sex-appropriate, they must realize that not only do they belong to one of these sexes, but they are subject to a similar set of expectations and reinforcement contingencies as others of their sex. Children may learn that other people are divided into males and females before they establish their own gender identities (Thompson, 1975). Thus children may proceed through an initial stage in which they acquire some knowledge of male- and female-appropriate behavior (via observational learning) but, not realizing they belong to one of these sexes, may fail to display a preference for imitating same-sex-appropriate behavior. Such a possibility should be tested. Once children attain gender constancy they do attend more to same-sex models (Slaby & Frey, 1975). However, developmental research that tracks the emergence of children's gender identities and their beliefs that they are expected to behave similarly to members of a particular sex and relates these variables to children's imitation of same- and cross-sex models is needed.

Because the present formulation emphasizes that children imitate responses that they abstract as appropriate for their sex as a group, it clearly assigns less importance to children's imitation of particular individuals (e.g., the like-sex parent) than do more traditional theories, especially Freudian theory (1949) or various other views that hold that children achieve sex typing via imitation of a warm and/or socially powerful parental figure (Hetherington, 1967; Mussen & Distler, 1959; Parsons, 1955; Sears, Rau, & Alpert, 1965). Although this is true, we do not mean to imply that children's sex typing is never influenced by their especially strong imitation of "significant others," for it undoubtedly is. However, we would expect that children who initially adopt responses by imitating a highly nurturant and/or dominant same-sex parent would ultimately drop the responses from their active repertoires if they eventually realize that no other same-sex individuals perform the responses but that many opposite-sex persons do.

Although in the first experiment boys and girls did not differ in their propensities to imitate abstracted same-sex-appropriate behavior, there was clear evidence in the second experiment that boys were more concerned than girls with matching their behavior to a model known to exemplify sex-typical behavior. This concurs with previous findings that a variety of socializing agents, including parents and peers, enforce stronger sanctions on boys than on girls for conforming to culturally defined sex-role prescriptions (Fagot, 1977; Fling & Manosevitz, 1972) and that boys are more likely to conform to peer pressure than are girls (Maccoby &

Jacklin, 1974). It may indeed be the case, as Lynn (1969) suggests, that boys become sex-typed through "masculine role identification" by acquiring and imitating cultural stereotypes of male-appropriate behavior learned by observing a variety of male figures both within and beyond the home. Girls, on the other hand, are less concerned with conforming to abstract standards.

Although this research indicates that imitation of abstracted sex-appropriate behavior is a plausible mechanism of sex role development, it is not implied that other factors (e.g., genetics, direct elicitation, and shaping of sex-typed behavior) are unimportant. The present formulation is probably a weak or inadequate explanation of early sex differences, say, those occurring in the first year or two of life. As early as age 1, there are sex differences in children's toy preferences, though the exact qualities of the toys (e.g., softness, faceness, number of moving parts, manipulability) responsible for the differences have yet to be isolated (Jacklin, Maccoby, & Dick, 1973). It seems unlikely that such early differences are due to abstracted differences about sex-appropriate behavior learned from observation of multiple models. The cognitive capacities required to notice that the sexes differ in their frequency of performing certain behaviors, to register the information in memory as male- or female-appropriate, and to learn that one is expected to conform to sex-appropriate role behavior take time to develop. Obviously, other factors must be involved in early sex differences.

One might wish to level the criticism against the present research that results are attributable to "demand characteristics" of the experimental procedures. In particular, it might be argued that using multiple models and testing the child in the presence of an experimenter who knew how the models had responded placed stronger demands on the child to display same-sex imitation than would exist under more natural circumstances and therefore that the results are artifactual. We would argue that many sex-typed behaviors are indeed public, with people in a position to view a performer's behavior just as aware as the performer of the sex-appropriateness of various response options in the situation. Consequently, it is entirely appropriate to examine imitation of sex-appropriate and -inappropriate behavior in the laboratory under circumstances similar to those that exist outside of it (i.e., in the presence of an observer—here, the experimenter). Moreover, the results of a third experiment conducted by the authors indicate that same-sex imitation does occur even in the absence of the experimenter.[2]

In the procedures used in the present study, endorsement of a choice preferred by the majority of one sex of model was confounded with rejection of the choice preferred by the majority of opposite-sex models. To illustrate, consider the models' choices in the high within-sex consensus condition of the first experiment. The endorsement by 100% of the male models of a particular item was, of course, coupled with implicit rejection of the item unanimously chosen by the female models. In any two-item forced-choice situation, endorsement of one item implies rejection of the other. In the present research, it is not possible to determine, for example, if a boy's imitation of responses endorsed by male models was a function of an active desire to emulate the male models or a wish not to display a choice indicated

---

[2] To examine the generality of some of the findings from the first two experiments reported, the authors conducted a third experiment. The design was identical to that of Experiment 2 of the present report. However, the procedure was altered in three major ways. First, peers instead of adults were used as models. Second, although the first, multiple-modeling phase of the study was conducted exactly as in Experiment 2 (with models indicating their preferences from among item pairs), the second modeling phase involved the modeling of novel action and verbal sequences rather than the modeling of additional item preferences. Third, the test for imitation involved leaving the child alone with the objects the model had used in displaying the action and verbal responses in the second phase, with instructions to "see if you can do some interesting things with them" while the experimenter was gone. Children's imitation of responses displayed by the model in the second phase was assessed by a time-sampling technique while the child was observed through a one-way vision screen for a 4-minute period. Results were virtually identical to those obtained in Experiment 2.

by the female models. In real-life settings, of course, many choice situations do exemplify the two-pronged situation facing children in our study where one choice was masculine and the other feminine. For theoretical reasons however, it would be interesting to develop a methodology that permits separate manipulation and assessment of a propensity to accept same-sex models' behavior, on the one hand, and a tendency to reject opposite-sex models' behavior, on the other. For instance, the stronger same-sex imitation shown by boys in the present research may stem from simultaneous desires to accept masculine behavior and to reject feminine behavior. Perhaps girls are also prone to accept same-sex behavior but are less repulsed by the thought of displaying cross-sex behavior.

Conclusion

The present research restores the same-sex imitation hypothesis as a plausible mechanism of social learning of sex differences, though in a modified conceptual context. Many important questions remain, however. These include the nature of the processes accounting for sex differences in the early years; the exact roles played by parents, peers, unfamiliar adults, and other classes of social models in the process; the sequencing of such cognitive accomplishments as children's realization that the social world is divided into males and females, that they belong to one of these groups, that they and others of their sex are subject to a similar set of expectations and reinforcing contingencies from the social environment; the relationship of these factors to children's observational learning and performance of sex-type behavior; and whether acceptance of same-sex behavior and rejection of opposite-sex behavior contribute equally to same-sex imitation in children of both sexes.

Telling Lies

Bella M. DePaulo and Robert Rosenthal
Harvard University

Men and women (20 each) were videotaped while describing someone they liked, someone they disliked, someone they were ambivalent about, someone they were indifferent about, someone they liked as though they disliked him or her, and someone they disliked as though they liked him or her. Accuracy at detecting that some deception had occurred was far greater than accuracy at detecting the true underlying affect, and people who were good at detecting that deception was occurring were not particularly skilled at reading the speakers' underlying affects. However, people whose deception attempts were more easily detected by others also had their underlying affects read more easily. Speakers whose lies were seen more readily by men also had their lies seen more readily by women, and observers better able to see the underlying affects of women were better able to see the underlying affects of men. Skill at lying successfully was unrelated to skill at catching others in their lies. A histrionic strategy (hamming) was very effective in deceiving others, and this strategy was employed more by more Machiavellian people, who also tended to get caught less often in their lies. Methodological considerations and systematic programs for future research are discussed.

Studies of skill at detecting lies from verbal and/or nonverbal cues usually focus on observers' ability to distinguish truthful responses from deceptive ones (e.g., Ekman & Friesen, 1974; Fay & Middleton, 1941; Harrison, Hwalek, Raney, & Fritz, 1978; Kraut, 1978; Littlepage & Pineault, 1978; Maier & Janzen, 1967; Maier & Thurber, 1968; Zuckerman, DeFrank, Hall, Larrance, & Rosenthal, in press; Krauss, Geller, & Olson, Note 1). Most published studies of human lie detection have found that people are substantially more accurate than chance at distinguishing veracity from mendacity (Fay & Middleton, 1941; Feldman, 1976; Harrison et al., 1978; Kraut, 1978; Littlepage & Pineault, 1978; Maier, 1966; Maier & Janzen, 1967; Maier & Thurber, 1968; Matarazzo, Wiens, Jackson, & Janaugh, 1970; Zuckerman et al., in press; see also DePaulo, Zuckerman, & Rosenthal, in press).

Discerning the degree of deceptiveness of a given response, however, is only one of several senses in which one might be said to be skilled at detecting a lie. In the case of a lie that involves the cloaking of a felt emotion with a feigned one, for example, skill at detecting the lie might be conceptualized as the ability to see through to the underlying affect that the deceiver is trying to hide. Using Ekman and Friesen's (1969) terms, this latter skill (identifying the concealed information) will be called *leakage* accuracy, whereas the former (recognizing that deception is or is not occurring) will be labeled *deception* accuracy. Although it might seem quite plausible that people who are especially good at detecting deceptiveness

We thank Russell A. Eisenstat and Susan Finkelstein for their help in collecting these data, and Judith A. Hall, Charles M. Judd, and Miron Zuckerman for their helpful comments on an earlier version of this manuscript.

will also be particularly skilled at reading leakage, this empirical question has not yet been addressed.

Two-tiered lies, in which an underlying or "true" affect is covered up by a dissimulated or "sent" affect, come in many varieties. For instance, they may involve the covering up of a positive emotion with a negative one or the covering up of a negative emotion with a positive one. In the few studies that have examined these kinds of lies (Ekman & Friesen, 1969, 1974; Feldman, 1976), the liars were always attempting to send positive cues. In the Ekman and Friesen (1974) study, for instance, nurses watching a very disconcerting film pretended to be watching a very pleasant one; in Feldman's study, teachers either liked or disliked a student who had performed either well or poorly, but in all conditions teachers were instructed to give only positive feedback to the student. We cannot know from these studies whether skill at detecting these sugar-coated lies (in which the feigned affect is positive) is related to skill at detecting lies in which the dissimulated affect is negative.

Paralleling our lack of knowledge about the generality of skills at detecting different kinds of lies is a lack of knowledge about the generality of skills at decoding different kinds of liars. For instance, are people who are especially skilled at identifying deceptiveness in women also particularly successful in recognizing deceptiveness in men?

The same kinds of questions that are asked about people trying to detect lies can also be asked about people who are attempting to spread lies. That is, are those persons who are especially adept at hiding their attempts at deception also especially successful at concealing their true feelings? Are people who are especially good at hiding an underlying positive affect also particularly skilled at hiding an underlying negative affect? Are people who are particularly transparent to women also especially transparent to men? Finally, are people who are good liars also good lie-detectors; that is, does it take one to know one?

To study these and other questions, we asked subjects to describe several people whom they knew: someone they liked, someone they disliked, someone they felt ambivalent about, and someone they felt indifferent about. To elicit deception, we asked them to describe the liked person while pretending that they really disliked him or her, and we also asked them to describe the disliked person while pretending that they really liked him or her. Thus, the design included underlying positive affect covered by feigned negative affect and underlying negative affect covered by feigned positive affect. It also included "pure" positive affect (liking), "pure" negative affect (disliking), and simultaneously occurring positive and negative affect (ambivalence). We asked the same subjects to return to judge these various descriptions. We believe that this paradigm, in which the observer is called upon to discriminate among a wide variety of affects, is more valid ecologically than is the scenario characteristic of most deception studies, in which the subject is asked merely to decide whether the speaker is lying or telling the truth.

This design also permitted us to study a particular style of lying—one that we call *hamming*. We think that a reasonable operational definition of a ham is someone who when pretending to like someone he or she actually dislikes, expresses *more* liking than when describing a person he or she really does like. Another kind of ham is one who exaggerates dissimulated disliking—that is, one who expresses more disliking when pretending to dislike someone he or she actually likes than when describing someone he or she really does dislike.

We wanted to know several things about this style of lying:

1. How common is this hamming strategy?

2. Is there really just one kind of ham, or might there be at least two? That is, are the people who exaggerate liking the same people who exaggerate disliking?

3. Does hamming work? That is, do people who ham it up get caught in their lies less frequently than those who use a less exaggerated style? Conceivably, hamming could backfire if an observer got the impression that the speaker "doth protest too much."

Because Machiavellianism is commonly thought to be linked to success at lying—

and in one study (Exline, Thibaut, Hickey, & Gumpert, 1970) has in fact been shown to be so related—we administered the Mach scale (Christie & Geis, 1970) to all of our subjects.

Method

Subjects

Subjects were 40 Harvard summer school students (20 males and 20 females) recruited for a study of "person descriptions" and paid for their participation.

Procedure

Subjects were asked to take 1 minute to describe each of the following persons: someone they liked, someone they disliked, someone they felt ambivalent about, and someone they felt indifferent about. (Ambivalence was defined as strong feelings of both liking and disliking; indifference was defined as no strong feelings of liking or disliking.) To elicit deception, subjects were also asked to describe the person they liked as if they really disliked him or her (like-as-though-dislike or LD condition) and to describe the person they disliked as if they really liked him or her (dislike-as-though-like or DL condition). These six descriptions were given in one of nine different orders (randomly assigned). Half of the subjects (10 males and 10 females, randomly assigned) described males; the others described females.

During the sessions, the experimenter remained behind a one-way mirror and videotaped the descriptions. Subjects were aware of this, and also knew that the experimenter was not informed of the sequence of their descriptions. They were urged to try to be very convincing in all of their descriptions.

From these descriptions, two hour-long videotapes were made, composed of the middle 20 sec of each description, plus rating pauses. The order of appearance of the senders on these tapes was randomized. (Only the middle 20 sec were used to keep the rating task—described below—to a more manageable length.) All subjects returned to judge one of these videotapes. Subjects always judged a videotape on which they did not appear. Subjects saw the videotape they were judging twice: the first time, they rated the descriptions on 9-point scales of liking, ambivalence, and deception; the second time, they rated the descriptions on 9-point scales of disliking, discrepancy, and tension.[1]

Accuracy Scores

An accurate decoder of deception would rate the deceptive descriptions as very deceptive and the pure like and dislike descriptions as not very deceptive at all. Thus, deception accuracy was defined as a subject's mean deception rating of the like-as-though-dislike and dislike-as-though-like descriptions minus their mean deception rating of the pure like (L) and dislike (D) descriptions. Separate subscores were computed analogously for the LD and DL descriptions and for the decoding of male and female speakers.

$$\text{Overall deception accuracy} = \frac{\text{deception ratings of LD} + \text{DL}}{2} - \frac{\text{deception ratings of L} + \text{D}}{2};$$

$$\text{Deception accuracy for LD} = \text{deception ratings of LD} - \text{deception ratings of L};$$

$$\text{Deception accuracy for DL} = \text{deception ratings of DL} - \text{deception ratings of D}.$$

Accuracy of encoding deception was defined analogously. A speaker whose lies were easily detected would be rated as very deceptive in the LD and DL conditions but not very deceptive at all in the liking or disliking conditions. Thus the encoding deception score was defined as the mean deception rating (by all judges who rated the speaker) of the LD and DL descriptions minus the mean deception rating of the pure like and dislike descriptions. Separate subscores were computed analogously for LD and DL and for judgments made by male and female observers.

$$\text{Overall deception accuracy} = \frac{\text{rated deception on LD} + \text{DL}}{2} - \frac{\text{rated deception on L} + \text{D}}{2};$$

$$\text{Deception accuracy for LD} = \text{rated deception on LD} - \text{rated deception on L};$$

$$\text{Deception accuracy for DL} = \text{rated deception on DL} - \text{rated deception on D}.$$

A judge more skilled at seeing underlying affects (decoding leakage) would rate a speaker pretending to like someone she/he actually disliked as disliking

[1] Scale endpoints were labeled as follows: speaker does not like (dislike) the person at all (1), speaker likes (dislikes) the person very much (9); speaker is not very ambivalent (deceptive, discrepant, tense) (1), speaker is very ambivalent (deceptive, discrepant, tense) (9). Discrepancy was defined as the simultaneous communication of several different emotions.

the person relatively more than liking him or her. Similarly, a more accurate decoder of leakage would see relatively more liking than disliking in the LD descriptions. Thus, LD accuracy was defined as a subject's mean liking rating of the LD descriptions minus his or her mean disliking rating of those descriptions; for DL, liking was subtracted from disliking. These scores were also computed separately for judgments of male and female speakers.

Leakage accuracy for LD
= liking ratings of LD
− disliking ratings of LD;

Leakage accuracy for DL
= disliking ratings of DL
− liking ratings of DL.

Encoding leakage (or betraying one's own true feelings) was defined as follows: for LD, the mean of judges' disliking ratings was subtracted from the mean of their liking ratings; for DL, liking was subtracted from disliking. Subscores were computed for judgments made by male and female judges.

Leakage accuracy for LD
= rated liking on LD
− rated disliking on LD;

Leakage accuracy for DL
= rated disliking on DL
− rated liking on DL.

Hamming

A person who hams in the DL condition expresses greater liking of the truly disliked person (whom he or she is pretending to like) than of the truly liked person. Thus, ham like was defined as judges' mean liking rating of a speaker's DL description minus their mean liking rating of that speaker's true or pure *like* description. Analogously, "ham dislike" was defined as judges' mean dislike rating of a speaker's LD description minus their mean *dislike* rating of that speaker's true or pure *dislike* description.

Ham like = rated liking on DL − rated liking on L;

Ham dislike = rated disliking on LD
− rated disliking on D.

Results

Accuracy

To examine the relative accuracy of communication of different kinds of lies (leakage, deception, LD, DL), a 2 (Leakage/Deception) × (LD/DL) analysis of variance (ANOVA) was computed, with repeated measures on both factors and accuracy scores as the dependent variable.

The main effect of leakage versus deception, $F(1, 36) = 132.04$, $p < .001$; $d = 3.83$,[2] showed that accuracy at recognizing when deception was occurring (deception accuracy) was substantially greater than accuracy at reading a speaker's underlying affect (leakage accuracy). Or, from the point of view of the speaker, the tendency to have one's attempts at deception accurately diagnosed was significantly greater than the tendency to have one's true underlying affect correctly identified. The main effect for LD versus DL and the interaction of LD/DL × Leakage/Deception were both very small, showing that accuracy at communicating L did not differ significantly from accuracy at communicating DL, and that the magnitude of the accuracy difference between leakage and deception did not vary significantly according to the particular affect that was feigned or concealed.

The overall level of deception accuracy differed significantly from zero, which is the value that would be expected under the null hypothesis of no accuracy, $t(38) = 5.06$, $p < .001$; $d = 1.64$. Thus, observers were significantly more accurate than chance at detecting when deception was occurring. Accuracy at reading the underlying affect was significantly *worse* than chance, however, $t(38) = 6.04$, $p < .001$; $d = 1.96$. This means that on the whole, observers tended to read the affect that speakers *intended* to communicate rather than the affect that speakers really felt.

Telling Different Kinds of Lies

The correlation between skill at detecting deception and skill at reading leakage was .05 for LD and −.11 for DL.[3] Both of these correlations were far from significant. Thus people who are especially good at knowing

---

[2] The index d is an estimate of the size of the effect expressed in standard deviation units (Cohen, 1977). As a rule of thumb, Cohen suggests regarding ds of .20, .50, and .80 as small, medium, and large effects, respectively.

[3] ns varied from 38 to 40 because there was one missing leakage subscore and one missing deception subscore.

when deception is occurring are not necessarily particularly skilled at knowing the speaker's true affective state.

In terms of encoding, however, the relationship between leakage and deception is strongly positive (for LD, Pearson's $r = .50$, $p < .01$; for DL, $r = .54$, $p < .01$). Thus people whose deception attempts are readily detected tend also to leak their true underlying feelings.

The ability to recognize deception when the speaker is hiding positive affect (LD) is not significantly related to the ability to recognize deception when the speaker is hiding negative affect (DL; $r = -.18$). However, the ability to read a leaked positive cue is very strongly related to the ability to spot a leaked negative cue ($r = .75$, $p < .001$). For encoding, the tendency to get caught telling an LD lie is correlated only .13 (*ns*) with the tendency to get caught telling a DL lie. The analogous leakage correlation is similarly small and nonsignificant (.19), showing that people who leak their underlying positive feelings don't necessarily leak their underlying negative feelings.

Different Kinds of Liars and Lie Detectors

Speakers who get caught lying by women also tend to get caught lying by men (for LD, $r = .62$, $p < .001$; for DL, $r = .54$, $p < .001$), and speakers whose leaked cues are picked up by women also have their leaked cues picked up by men (for LD, $r = .76$, $p < .001$; for DL, $r = .77$, $p < .001$). Similarly, observers who are skilled at reading the leakages of women also tend to be skilled at reading the leakages of men (for LD, $r = .72$, $p < .001$; for DL, $r = .78$, $p < .001$). However, skill at knowing when women are lying is *not* significantly correlated with skill at knowing when men are lying (for LD, $r = .06$; for DL, $r = .27$).

Skill at Telling Lies and Skill at Telling Lies: Are They Related?

The four different kinds of ability to tell (detect) lies (detecting leaked liking and leaked disliking; detecting LD and DL lies) were correlated with the four different kinds of ability to tell (get away with) lies. The 16 correlations ranged from .20 to −.24, and all were statistically insignificant. The median correlation was exactly zero. Thus, the ability to get away with one's own lies seems to be completely unrelated to the ability to catch other people in their lies.

Hamming

Only 13 of the 40 subjects earned *ham like* scores greater than zero; only 10 earned *ham dislike* scores greater than zero. Thus, the tendency to express more liking (or disliking) when lying than when really liking (or disliking) was not particularly common in this sample. Further, *ham like* scores were not significantly correlated with *ham dislike* scores ($r = .24$), suggesting that there are probably at least two different kinds of hams. Finally, hams who exaggerate feigned liking and hams who exaggerate feigned disliking are both tremendously successful at their deception attempts (between *ham like* and encoding deception, or getting caught in one's attempts to lie, $r = -.60$, $p < .001$; the r for ham dislike was identical.

Machiavellianism

A median split was calculated for Machiavellianism scores, and a Machiavellianism (High/Low) × Type of Affect (LD/DL) × Type of Lie (Leakage/Deception) ANOVA was computed with encoding scores as the dependent variable. A main effect for Machiavellianism showed that high Machs were slightly more successful at getting away with their lies than were low Machs, $F(1, 36) = 3.04$, $p = .09$; $d = .58$. The interaction of Machiavellianism with type of affect showed that high Machs were especially successful at deceiving when pretending to dislike someone they really liked, $F(1, 38) = 5.96$, $p < .05$; $d = .79$. The interaction of Machiavellianism with type of lie was not significant.

An analogous 2 × 2 × 2 ANOVA was computed using decoding scores as the dependent variable. The main effect for Machiavellianism was very small, and the interactions of type of

lie and type of affect with Machiavellianism were also nonsignificant.

In this sample, Machs also tended to be hams—significantly so for *ham like* ($r = .31$, $p = .055$), though only weakly for *ham dislike* ($r = .14$, *ns*).

Discussion

Consistent with at least ten previous studies of human lie detection (Fay & Middleton, 1941; Feldman, 1976; Harrison et al., 1978; Kraut, 1978; Littlepage & Pineault, 1978; Maier, 1966; Maier & Janzen, 1967; Maier & Thurber, 1968; Matarazzo et al., 1970; Zuckerman et al., 1979), we found that observers were able to identify accurately the occurrence of deception. However, we also found that observers were markedly unable to see through to a speaker's underlying affect when that affect was covered over by some other dissimulated display. Feldman (1976), too, in a study that examined both leakage and deception skill, found that observers could pick up the deception cues but not the underlying affect. Perhaps a convergent finding is the near-zero correlation between identifying deception and reading leakage. Apparently, an observer can have a keen sense of when "something fishy is going on," without necessarily being able to differentiate the feigned feeling from the true affect.

Except for the very small relationship between skill at hiding liking (LD) and skill at hiding disliking (DL) ($M\ r = .16$), the ability to lie successfully appears to be a fairly general one. People who effectively mask their deception attempts also effectively conceal their true affective states ($M\ r = .52$). Further, people who are especially adept at fooling women (whether in terms of leakage or deception) also tend to be particularly skilled at deceiving men ($M\ r = .67$).

There was also a considerable degree of consistency in the ability to detect different kinds of leakages. People who were especially skilled at noticing an underlying negative affect were also particularly adept at discerning an underlying positive affect. Similarly, people who were especially likely to read the leakages of women were also especially likely to read the leakages of men ($M\ r = .75$).

The tendency to read leaked cues, however, is not significantly related to the ability to recognize the occurrence of deception. Further, the ability to detect deception appears to be a much more disparate set of skills than is the ability to perceive leaked affects. People who can tell that a lie is occurring when liking is being concealed cannot necessarily detect a lie when disliking is hidden. Further, observers who know when women are lying do not necessarily recognize dissimulation by men. Using a "To Tell the Truth" format, Littlepage and Pineault (1978) also found a near-zero correlation between the ability to point to the impostrous male panelists and the ability to identify the impostrous women. Perhaps observers operate on the assumption that there is a single set of clues that tip people off to deception, when in fact women's deceit is revealed in ways different from men's. There is already some evidence suggesting that people's lay theories about clues to deception are not particularly accurate (Ekman & Friesen, 1974; Kraut, 1978; Maier & Janzen, 1967; Krauss et al., Note 1). The second part of the hypothesis, about sex differences in clues to deception, is still essentially an unanswered question. With the exception of a study by McClintock and Hunt (1975) and one by Mehrabian (1971, Experiment 2), most studies of deception cues tend to use subjects of only one sex or to exclude sex as a factor in the analyses (Ekman & Friesen, 1972; Ekman, Friesen, & Scherer, 1976; Harrison et al., 1978; Knapp, Hart, & Dennis, 1974; Kraut, 1978; Streeter, Krauss, Geller, Olson, & Apple, 1977). Both Mehrabian (1971) and McClintock and Hunt (1975) present evidence suggesting that there may in fact be sex differences in at least some of the behaviors emitted during deception.

The relative homogeneity of encoding skills compared to decoding skills is consistent with Kraut's conclusion that people are consistently successful or unsuccessful as liars but are not so consistent as lie detectors. The exception in our data to the general consistency of skills in encoding lies was the very weak relationship between lying successfully about underlying positive feelings (LD) and lying successfully about underlying negative feel-

ings (DL). The importance of the particular kind of affect that is being hidden or dissimulated was also apparent in (a) the weak correlation between detecting LD lies and detecting DL lies; (b) the nonsignificant correlation between exaggerating (hamming) feigned liking and exaggerating feigned disliking; and (c) the interaction between Machiavellianism and the type of affect being encoded. This suggests that conclusions drawn from studies involving just one variety of hidden affect or one kind of "sent" cue may in some cases be of limited generality.

The ability to lie effectively to others was entirely unrelated to the ability to detect the lies of others. Zuckerman et al. (in press) reported a similarly low and insignificant correlation (.20) between encoding and decoding deception. These results are consistent with the results of 17 studies of pure (nondeceptive) nonverbal communications: for those studies, the median correlation between encoding skill and decoding skill is .16 (DePaulo & Rosenthal, in press). The ability to express one's emotions accurately appears to be quite distinct from the ability to interpret the emotions of others accurately, whether those emotions are real or dissimulated.

The Machiavellian subjects in our study, like those in the Krauss et al. (Note 1) study, were not especially skilled at detecting deception; like the Machs in the study by Exline et al. (1970), however, they were fairly successful as liars. We also found that Machs seem to favor an especially theatrical style of deceiving, particularly when feigning positive regard: they, more than their less Machiavellian counterparts, tend to be hams when they lie. Moreover, the hamming strategy appears to work quite well: people who tend to exaggerate sentiments of liking that they do not really feel, as well as people who exaggerate feigned feelings of disliking, are much less likely to get caught in their lies than are the less histrionic sorts. The future of the study of hamming looks promising. Already there is evidence suggesting both sex differences (Rosenthal & DePaulo, in press) and developmental differences (Feldman, Jenkins, & Popolla, in press) in this style of lying.

Methodological Considerations

The present study points to the advantages of distinguishing deception from leakage, of sampling a wide range of encodings, and of using designs that completely cross the affects that are actually experienced with those that are dissimulated or "sent." These design features should help to separate deceptive messages from discrepant but nondeceptive ones and to distinguish deception from stress or from unpleasant affects.

In our study, the lie detectors were the same persons who had previously served as liars; hence, they might have been predisposed to use particular kinds of cues or strategies. Moreover, in our study as in earlier investigations (e.g., Streeter et al., 1977), judges knew exactly what proportion of the time the senders would be lying. Research paradigms in which the judges are not given this information—and, furthermore, are not specifically informed about the content of the lie—might be more realistic. Finally, comparisons of posed deceit with spontaneous lies will shed light on the generalizability of the kinds of deceptions we most often stage in our laboratories, as will a more extensive sampling of deceptions in naturalistic settings.

Future Research in Deception: Toward a More Programmatic Approach

Studies of the abilities to detect lies and to deceive successfully comprise just one area in the psychological literature on deception. (We concern ourselves here only with lie detection that is unaided by physiological measurements or detection devices; for a more physiologically oriented review, see Lykken, 1974, 1979, Orne, Thackray, & Paskewitz, 1972, or Podlesny & Raskin, 1977.) A second line of inquiry looks at accuracy of lie detection as a function of differential access to different channels or modalities such as the face, the body, the tone of voice, the words, and various combinations of these cues (e.g., Ekman et al., 1976; Ekman & Friesen, 1969, 1974; Feldman, 1976; Littlepage & Pineault, 1978; Streeter et al., 1977; Zuckerman et al., in press; Krauss et al., Note 1). The appeal of these studies probably derives in part from

the suggestion that certain channels, such as the face, that under ordinary circumstances are extremely informative, can be especially misleading under conditions of deception. These studies demonstrate the kinds of information that *can* be gleaned from a particular channel when access is restricted to that channel; a further step would be to demonstrate whether this same information is in fact extracted when information from other channels is available, too (cf. Streeter et al., 1977). If it can be established that particular channels are especially misleading under conditions of deception, it might then be asked whether people adjust their attentional strategies in ways that seem to acknowledge these modality effects (DePaulo, Rosenthal, Eisenstat, Rogers, & Finkelstein, 1978), whether particularly skilled lie detectors are especially likely to make these adjustments, and whether attentional instructions or training procedures can increase accuracy of detection.

A third approach has concerned itself with identifying particular cues, such as smiling, speech errors, and pitch, which distinguish deceptive from nondeceptive responses (e.g., Ekman et al., 1976; Ekman & Friesen, 1972; Harrison et al., 1978; Knapp et al., 1974; Kraut, 1978; Luria, 1932; McClintock & Hunt, 1975; Mehrabian, 1971; Streeter et al., 1977; Alker, Note 2). This line of research might be advanced by a consideration of the relationships among (a) the cues that actually do distinguish truth from deception; (b) the cues that people say they use to distinguish truth from deception; and (c) the cues that people actually do utilize in their judgments (see Baskett & Freedle, 1974; Kraut, 1978).

Studies of veridical clues to deception, when they do examine comparable clues, sometimes yield disappointingly inconsistent results. The question "What are the clues to deception?" is probably too broad; instead, we may need to ask, "What are the clues to which kinds of deceit by which kinds of deceivers to which kind of receivers in which kinds of situations?"

A Matrix for Generating and Organizing Research on Deception

We can start, then, by sketching a taxonomy of lies, liars, lie detectors, and social settings. Then, by locating specific studies of clues to deception within this matrix of lie types, setting types, deceiver types, and detector types, perhaps higher order consistencies will emerge. This four-dimensional approach should be equally relevant to the other two lines of inquiry. Thus, for example, we might want to know whether certain channels are especially misleading when communicating certain kinds of lies, or whether people are especially effective liars or lie detectors in same-sex or same-status dyads.

Among the many kinds of lies are ordinary white lies, proffered in the service of smoothing social interaction, lies of self-aggrandizement for purposes of impression management or personal gain, and lies in which the deceived party is the intended beneficiary, as in physicians' careful cloaking of grim prognoses or parents' imaginative fabrications about sex and death.

Lies may involve facts that may or may not be verifiable by external criteria (as in police investigations), or they may involve attitudes or opinions or feelings about oneself or others. Lies vary also in the degree of guilt or stress that they cause for the deceiver, the degree of involvement that they engender in the topic of the lie, the consequences of getting caught in the lie, and whether the lies were planned and rehearsed or unpremeditated.

An important dimension of social settings is the degree of normative or situational support that they offer to the deceiver. Those who lie to parole officers (especially in "tough" neighborhoods) or to captors in a military setting probably find their deceit more readily justifiable than those who lie to priests, doctors, and close friends. Structural characteristics of contexts, such as the degree of formality or informality or of democracy or autocracy, may also importantly affect the cues used to detect deceit, the modalities used to convey deceit, and the overall ease with which lies are discovered or perpetuated. Still another important aspect of social settings is the people in those settings—the number of participants, their structural relationship to the deceiver and the deceived (e.g., whether they are outside observers or are directly involved in the interaction); their affective

relationship (whether they are more closely allied with the deceiver or with the deceived); and their expectations about the probability of occurrence of deception.

Relevant characteristics of both the deceiver and the detector include demographic characteristics (e.g., age, sex, race, socioeconomic status); personality characteristics (e.g., adjustment, anxiety, Machiavellianism); social competence (e.g., nonverbal sensitivity); and cognitive competence (e.g., intelligence). The liar's and the lie detector's appraisal of success in deception (i.e., whether they view effective liars as clever and well adjusted or as immoral and psychopathic) might also predict the outcomes of deceptive transactions. These effects are probably best studied as two-way interactions in designs that cross characteristics of the deceiver with analogous characteristics of the detector.

Trait versus state aspects of lying might also mediate deception effects—that is, the deceiver may be an inveterate liar or an occasional liar who at the present moment is or is not telling the truth; similarly, the lie detector may be a chronic paranoid or a naive and unsuspecting soul who at the present moment is or is not suspicious of the deceiver's intent. The relationship of the deceiver to the deceived—spatially; temporally (is this a one-time meeting or will they see each other again in the future?); and personally (are they strangers, friends, intimates, or enemies? what is their relative status and power?)—should also be considered in future research efforts.

New JPSP Format Delayed Until April

Recent issues of this journal carried an announcement that the *Journal of Personality and Social Psychology* would appear in January 1980 under new policies and in a new sectioned format. However, in order to publish the backlog of manuscripts accepted under present policies, the first three issues of 1980 will continue to carry articles accepted under Clyde Hendrick's Acting Editorship.

This journal will appear in April as a sectioned journal edited by Melvin Manis, Ivan D. Steiner, and Robert Hogan, as previously announced.

Attributional Information Processing: A Response Time Model of Causal Subtraction

Eliot R. Smith
Department of Sociology
University of California, Riverside

Frederick D. Miller
New York University

Response time measures have been used occasionally in social psychology, but rarely as direct probes of information processing. A study collecting response time data in a near-exact replication of McArthur's classic attribution study sheds light on the information processing involved in subjects' responses. The process is analyzed into two stages: (a) encoding or comprehension of the stimulus sentence and the consensus, distinctiveness, and consistency information and (b) attributional processing per se. In the second stage, response time analyses suggest that perceivers operate by *subtracting* causes from an initial set to arrive at a response, rather than by adding causal components (person, stimulus, and circumstances) until an adequate cause is obtained. Subtraction is theoretically related to the salience model of attribution. Response time measures promise to expand greatly the ability of social psychologists to build process models of causal attribution and other kinds of social perception and cognition.

Researchers on causal attribution have expressed increased interest recently in the formulation of models of attributional processing, as distinct from the prediction of attributional judgments or outcomes (Pryor & Kriss, 1977). A model of attributional information processing permits the prediction of social cognition and behavior in a range of new situations (assuming that the same process will continue to operate), whereas studies that just measure attributional outcomes are hampered by the fact that any particular outcome could be generated by a large number of different processes, with different implications for new situations (Anderson, 1976, p. 11). In addition, information-processing models of attribution may find a place within the general models of human cognitive functioning that are currently being developed in cognitive psychology (e.g., Anderson, 1976; Schank, 1975), leading us closer to a fruitful union of cognitive and social psychology (Simon, 1976; S. Taylor, 1976).

Response time (RT) measures, a frequently used tool for the development of cognitive process models, are just beginning to be used in social psychology. Pryor and Kriss (1977) used response times to validate a manipulation of salience or availability: they demonstrated that the first noun presented in a sentence (whether subject or object) was more quickly recognized in a response time test than the second noun presented. They concluded that the first noun was more available. Markus (1977) used response times to demonstrate that people with "self-schemata" relevant to a given adjective identified those adjectives more quickly than did subjects without such self-schemata. However, social psychologists have not yet used response time methods to probe processing directly (cf. Posner, 1978), as cognitive psychologists have used them (e.g., Carpenter & Just, 1975; Schneider & Shiffrin, 1977; Shiffrin & Schneider, 1977).

Two of the ways in which response time measures can probe processing will be con-

This research was supported by the University of California Academic Senate and by a New York University Challenge Grant.

sidered here (for a review, see D. Taylor, 1976). First, the time for a response may vary depending upon experimentally manipulated factors. The studies by Carpenter and Just (1975) on verification of affirmative and negative sentences illustrate this possibility. Negative sentences take longer to verify, and this can be interpreted to indicate that they are transformed to affirmative before the verification process begins. The second possibility is that a relationship may exist between the content of a response and the time needed for the response. For example, the time for "not match" judgments about the identity of complex stimuli is greater than for "match" judgments in the data of Trabasso, Rollins, and Shaughnessy (1971). This is used as evidence for a serial feature-matching process, in which the features of the stimuli are compared for identity one at a time, with a mismatch of features leading to several time-consuming processes such as preparing a "not match" response and rechecking features.

The current study uses these two types of analysis to examine the processes involved in causal attributions in a replication of the now-classic McArthur (1972) attribution study. McArthur presented her subjects with sentences like "Sue is afraid of the dog," followed by three types of additional information. High (low) consensus is information about the actions of other people: "Almost everybody (nobody) else is afraid of the dog." High (low) distinctiveness concerns this person's responses to other objects: "Sue is not afraid of almost any other dog (is afraid of almost every other dog)." High (low) consistency describes the past history of the response: "In the past Sue has almost always (never) been afraid of the dog." The three types of information are manipulated in a $2 \times 2 \times 2$ design, and subjects' responses as to what caused the event to occur are obtained. McArthur's dependent measure offers subjects a choice of four causal possibilities:

1. Something about the *person* (e.g., Sue) probably caused her to make response X (e.g., be afraid) to stimulus X (e.g., the dog).

2. Something about *stimulus X* probably caused the person to make response X to it.

3. Something about the *particular circumstances* probably caused the person to make response X to stimulus X.

4. Some combination of 1, 2, and 3 above probably caused the person to make response X to stimulus X. (The subject is asked to check either $1 + 2$, $1 + 3$, $2 + 3$, or $1 + 2 + 3$; McArthur, 1972, p. 175.) McArthur's study was originally designed to test Kelley's (1967) analysis of variance (ANOVA) model of attribution and has been extremely influential in the attribution research tradition.

The addition of a response time measure to this study will allow two types of analysis. The first purpose of this study is to investigate the influence of consensus, distinctiveness, and consistency information on the time taken for attributional processing. It may be hypothesized that certain patterns of information will be easier to encode and process than others. For example, one prediction is that certain "standard" patterns of information (Orvis, Cunningham, & Kelley, 1975, suggest the three patterns high/high/high consensus/distinctiveness/consistency, low/low/high, and low/high/low) are consistent with perceivers' expectations and should be more quickly processed than other patterns. In general, relationships between the manipulated information factors and RTs give insight into subjects' encoding and processing of the information.

The second aim of this study is to examine the relations between the content of causal judgments and the time taken to arrive at them in order to clarify the procedure the attributor uses. Several procedures are possible. One is a "look-up" process, in which the perceiver refers to memory for a particular attributional response that is stored with each possible configuration of information (or at least with some of the possible patterns), much as one looks up a name in a phone book to locate a number (the response). That is, one may have stored the fact that low/low/high information points to the person as cause; that high/high/high implies stimulus; that low/high/low implies circumstances, and so forth. The process of looking up each information configuration should take about the same amount of time, yielding a prediction of no relation between

mean RT and the content of the response. Alternatively, one could predict (following Orvis et al., 1975, p. 606) that perceivers may have stored *only* these three "standard data patterns," so that responses of person, stimulus, or circumstance attributions to those patterns are quick, whereas other responses are slower, since the perceiver must engage in further processes (perhaps comparing the observed information pattern to more than one of the standard patterns to arrive at a compromise response).

A second type of process is additive. Here the perceiver begins by considering a single causal factor (most likely the person) and adds other factors to it (a process that takes time) when and if the available information indicates that they are required. That is, if a quick check shows that the current response is adequate, it is given. On the other hand, if a mismatch appears between the tentative causal response and the given information, another component must be added to the tentative response (e.g., changing from person to person plus circumstances), and a response change has been found to require processing time (cf. Newell, 1973, p. 490; Trabasso et al., 1971). It may also be true, as Trabasso et al. (1971) found, that the detection of a mismatch between response and information requires more time than detection of a match. The overall prediction is thus that single-component responses (or at least the person response) should be quick and multi-component responses should be slower; ideally, this model would give a *positive,* linear relationship between the number of components in the response and the response time, if detecting a mismatch and adding any component to the response takes the same increment of time. This sort of model is suggested by the way in which psychologists tend to think of attributional responses. Examples are the treatment by Orvis et al. (1975) of information patterns for the three single-component responses as "standard," and Kassin and Hochreich's (1977) labeling of single-factor responses as "simple" and multi-factor responses as "complex."

A third suggested process is the inverse of the second. Instead of beginning with a single component as a tentative response and engaging in processing that may add components to the response, the perceiver might begin with a three-component tentative response and engage in processing that may delete or subtract components. As in the second model, the subject is presumed to check the tentative response against the given information; again, a match is presumed to lead quickly to the emission of that already prepared response. A mismatch leads to processing, the effect of which is to delete a causal component from the response. As in the second model, the changing of the tentative response is presumed to be time-consuming. The overall prediction is that the three-component response of person plus stimulus plus circumstances should be the quickest and single-component responses the slowest, as the latter involve the most deletions (two). Ideally, one would obtain a *negative,* linear relationship between the number of causal components in the response and the response time, indicating that the mismatch detection and subtraction of any component from the response takes about the same amount of time. The predictions of these three models are summarized in Table 1.

Thus this study will investigate the relationship between the reported attribution and the time taken to report that attribution to enable a choice among the three processes suggested above. From McArthur's (1972) study and many other investigations we know the content of the causal attributions that subjects produce for each information combination. However, each of the three processes outlined above could generate that same set of outcomes (cf. Anderson, 1976, p. 11), and thus the entire body of prior research gives inconclusive evidence as to the nature of the process, the issue considered here.

Method

The procedure of this study generally followed that of McArthur (1972), which should be consulted for further detail. To permit the recording of RTs, the study was conducted with the aid of a computer. The stimulus materials (sentences) were displayed on a televisionlike cathode-ray tube screen and subjects reported their attributions by pressing response keys. Timing started when the

Table 1
Response Time Predictions for Three Models

Model	Response		
	1-component	2-component	3-component
Look up	←Same time for any response→

Additive	Short	Moderate	Long
Subtractive	Long	Moderate	Short

[a] Orvis, Cunningham, & Kelley, 1975.

sentence appeared and ended when a key was pressed; the times thus include reading and comprehension time as well as attributional processing. The computer controlled the generation and presentation of stimuli, recorded the responses and RTs, and output the data for analysis.

Materials

The stimulus materials are described above and in McArthur (1972). The 32 sentences used fall into four categories based on the type of verb: action, accomplishment, opinion, and emotion. Like McArthur, we will be concerned primarily with the distinction between the first two categories versus that between the third and fourth (manifest vs. latent verbs).

As in the McArthur study, consensus, distinctiveness, and consistency information were manipulated by additional sentences that followed the sentence describing the event that was the object for attributions. These sentences were always presented in the same order for two reasons: (a) to replicate McArthur's study, her procedure was followed in this regard, and (b) the different weights that the three items of information have when their order is randomized (Ruble & Feldman, 1976) are not of central concern here. We are chiefly interested in the response times rather than in the responses' content, as long as the responses indicate that a successful replication of McArthur's results has been achieved.

The question to which subjects responded was that used by McArthur: "Your task is to decide, on the basis of the information given, what probably caused the event to occur" (1972, p. 174). McArthur's response format was slightly modified in this study in order to treat all responses more symmetrically and to avoid the second level of response necessitated when "combination" was chosen in the original format. Just three response keys were used. They represented the person, stimulus, and circumstances causal factors, and subjects were permitted to respond with just one, any two, or all three of the keys to indicate combination responses. Subjects in pilot testing indicated that this response format posed no difficulty, so it was adopted for the data collection. Subjects began each trial with three fingers of the preferred hand resting on the three keys. Timing stopped when the computer sensed the first key press; if any further key presses took place within one-half sec, they were recorded as part of a multikey combination response (the keys of a combination response were nearly always pressed simultaneously by subjects). The assignment of the labels *person*, *stimulus*, and *circumstances* to the three keys was counterbalanced between subjects.

Procedure

The 24 subjects, paid undergraduate volunteers, were run individually. After subjects had been instructed in the use of the response keys and given practice on 8 practice sentences of the type used in the study, the actual trials began. On each trial, the subjects read the sentence and additional consensus, distinctiveness, and consistency information; responded with an attribution by pressing a key or keys; and then signaled when they were ready for the next trial. The intertrial interval was not timed. Trials were administered in two blocks of 16 each, with a 3–5 min rest between blocks. The 32 stimulus sentences were given to each subject in a different random order; thus no systematic order effects can exist in the data.

Analyses

The results were analyzed in what is effectively a Verb Type (Manifest vs. Latent) × Consensus × Distinctiveness × Consistency (2 × 2 × 2 × 2) analysis of variance (ANOVA), with the appropriate interactions with subject and with sentence forming the components of the denominator mean square for quasi-F ratios. Such tests confirm that an effect is reliable not only with a new sample of subjects (using the same experimental materials, e.g., sentences) but with a new sample of subjects and a new sample of materials as well. The routine use of simple F statistics with only subject as an error term provides no evidence for the replicability of effects beyond the specific set of experimental materials used, a practice Clark (1973) criticizes for language research. Kenny and Smith (Note 1) de-

scribe the technical aspects of this analysis more fully, including the procedure for assigning information conditions to sentences for each subject and for recovering them in the analysis.

Analyses were performed for several dependent variables, including (a) response times; (b) the response categories McArthur used, which were person, stimulus, circumstances, person plus stimulus, and "other" attributions (all other types combined); and (c) the person, stimulus, and circumstances components of the response. The components (i.e., the responses on the three keys treated as three separate dependent variables) have the advantage that they are statistically independent, which is not the case with McArthur's categories, where each response has to fall into exactly one category. Furthermore the analysis of components may more accurately represent the content of subjects' responses. For example, a response of person plus circumstances will be counted here as (both) a response involving person and a response involving circumstances, whereas the original category system would treat such a response with "others" as unrelated to either person or circumstances.

Logs of RTs were analyzed because a slope of nearly 1 related the raw RT cell means to the cell standard deviations. Winer (1970, p. 400) suggests using a log transformation in such cases, and it practically succeeded in eliminating the cell mean–standard deviation relationship.

Results

Response Times

The analyses of variance by information condition using log response time as the dependent variable yielded only one significant effect, a distinctiveness–consistency interaction. Under high distinctiveness – high consistency and low distinctiveness – low consistency, responses were significantly slower ($M = 13.44$ sec) than under the other two combinations, $M = 12.32$ sec, quasi-$F(1, 7) = 18.9$, $p < .01$. The verb-type factor had no significant main effects or interactions affecting response time—thus manifest and latent verbs do not seem to differ in the amount of time required for attribution.

Relations Between Response and Response Time

Collapsing across information conditions, one can analyze the relationship between the response given by the subject and the RT for that response. This analysis should indicate the attributional procedure followed by the subject, as discussed above. Ignoring conditions in this analysis is appropriate, since subjects receive conditions in a random order and so do not know until the stimulus appears which condition it represents. Thus subjects are unable to apply different attributional procedures for different conditions. (In addition, if subjects did use different procedures for different conditions, one would expect to find only confused relationships between responses and RTs, as a result of averaging across different procedures.) The results of this analysis are shown in Tables 2 and 3. The data show a very clear negative, linear trend in log response time depending upon the number of components in the response. Subjects take the shortest time, approximately 11.07 sec (7.009 in log units) to make the "complex" person-plus-stimulus-plus-circumstances response, and the longest time, approximately 13.64 sec, for the "simple" single-factor responses. Each component that is subtracted adds approximately .097 in log units to the RT. Deviations from this linear trend are nonsignificant, so one would not gain by assuming that different components might take different amounts of time to subtract.

Table 2
Response Time by Response Analysis, Using Logs

Response	*M* response time	
	Log	Sec
Person	7.223	13.71
Stimulus	7.209	13.52
Circumstances	7.222	13.69
Person + stimulus	7.142	12.64
Person + circumstances	7.171	13.01
Stimulus + circumstances	7.116	12.32
Person + stimulus + circumstances	7.009	11.07

Attributions

The results with McArthur's (1972) dependent measures paralleled those of the earlier study nearly exactly, except that the analyses in this study have less power be-

Table 3

cause of their reliance on quasi-*F* ratios rather than simple *F*s. Across the 28 ANOVA effects in the two studies (4 Dependent Measure Categories × 7 Main Effects and interactions of the informational variables), 9 effects were significant in both studies; 10 effects were significant in McArthur's study and not here, and none was significant here and not in McArthur's investigation. All effects that were significant in both studies had mean differences in the same direction.[1]

Analyses of the person, stimulus, and circumstances components produced somewhat simpler results, as predicted. In contrast to the analysis of the McArthur dependent measures, no interaction effects were found with the components. Person attribution was increased by low consensus, low distinctiveness, and high consistency. Stimulus attribution was increased by high consensus. Circumstances attribution was increased by low consistency. Means and quasi-*F* tests appear in Tables 4 and 5.

Table 4
Means for Significant Effects of Informational Factors on Causal Components

Low	.724	.471	
Distinctiveness			
High	.523	*ns*	*ns*
Low	.753		
Consistency			
High	.714	*ns*	.276
Low	.562		.654

Discussion

The near-exact replication of McArthur's results (when her measures are analyzed) in this study indicates that the changes in design (a different set of sentences and a new response format) did not materially affect the results of subjects' information processing. However, the addition of the response time dependent measure yields valuable information about the processes that underlie the attributional judgments made by subjects. The results will be discussed in the context of a proposed model of information processing containing two stages, the times for which are added to produce the total RT (cf. D. Taylor, 1976). The stages are *encoding* the presented information (stimulus sentence plus the three types of information) and *attribution processing*. The logical necessity for these two stages in a model for the current task is clear. The subject must begin by reading and understanding the stimulus sentences, transforming them into some internal representation in memory. This encoding stage must take time. Second, though some inferences about causal relations may take place during encoding (cf. Kintsch, 1974; Schank, 1975), the encoded information must still be used in some fashion to generate and check an appropriate response to the attributional question; three alternative processes for this stage were outlined above. Of course, other processing may occur as well—for example, the generation of the

[1] The results of these analyses of McArthur's dependent variables are not presented in full; they are relied upon simply to establish that a successful replication of McArthur's results has occurred. The analyses reported in the next paragraph and in Table 3 represent a simpler and more direct presentation of the attributional results than do the analyses of McArthur's dependent variables.

physical movements involved in making the response—but if their time is roughly constant across conditions, the conclusions drawn for the two-stage model are not affected (only the grand *M* RT will be changed). The current data cannot indicate whether the two stages are purely sequential. At least some encoding must precede attributional processing, but the two stages might overlap to some extent; our conclusions are unaffected by this variable. (For a comparable two-stage model for a concept verification task—comprehension and processing—see Trabasso et al., 1971.)

Table 5
Quasi-F *Tests for Significant Effects of Informational Factors on Causal Components*

Effect	*df*	*F*	*p* <
Consensus on person	1, 13	17.36	.001
Consensus on stimulus	1, 11	23.03	.001
Distinctiveness on person	1, 6	81.52	.001
Consistency on person	1, 9	20.64	.001
Consistency on circumstances	1, 13	47.68	.001

Note. All effects not shown are not significant at the .05 level. Denominator *df*s for a quasi-*F* test depend on the data and are not simply the *df* for a denominator *MS* in the analysis of variance table.

Encoding

The effects of the informational variables on RT can be interpreted as representing encoding or comprehension processes. In particular, since distinctiveness and consistency interact with this particular task, they must be presumed to influence the same stage (Sternberg, 1969; D. Taylor, 1976). The reasoning behind this conclusion is based on the fundamental assumption of RT models, that of additive stages. If two factors affected the times of *different* stages, their effects on the total RT would be additive (and thus noninteractive). Hence, factors that interact must influence the time of a single stage. Consensus does not interact with the other two information factors, but this need not cause its assignment to a different stage (D. Taylor, 1976, p. 190).

The distinctiveness–consistency information combinations high–low and low–high take less time to encode than do the other two combinations. Why is this? Subjects' expectations may provide an answer. In two studies Orvis et al. (1975) presented subjects with single information items (consensus, distinctiveness, or consistency alone) and asked the subjects to predict the levels of the other information factors. Subjects given high consistency predicted that distinctiveness would be low, in both of the studies by Orvis et al.; subjects given low consistency predicted that distinctiveness would be high in both studies. Similarly, high distinctiveness led to predictions of low consistency (in only one of the two studies, however), and low distinctiveness led to predictions of high consistency (in both studies). Thus, in seven of these eight comparisons the high–low and low–high combinations seem to go together or to be consistent with subjects' expectations. They are therefore partially redundant (carry less information) and so should be encoded more quickly. The other two combinations, high–high and low–low, do not have this redundancy; they tend to contradict subjects' expectations and should take more processing time to encode. The distinctiveness–consistency interaction effect on overall RT is thus explicable as a function of encoding processing.

Attribution

The second stage is the inference of a cause using the encoded forms of the presented information. The negative relationship obtained between the number of components in the response and the response time suggests that the process is subtractive. The subject appears to start by considering person plus stimulus plus circumstances as a cause. If that is found to be the appropriate response, it is given very quickly; otherwise, components are successively subtracted from that set as they are found to be unnecessary. Each detection of a mismatch between the tentative response and the information, followed by the subtraction of a component, takes about the same amount of time (.097 in the log scale). Thus, two-component causes all take somewhat more time to give than the three-component response, and single-component causes take longest of all.

The pattern of results weighs against the additive model of attributional processing, which predicts that single-component responses should be the quickest rather than the slowest. The information look-up model is also inconsistent with the results; this model postulates that the perceiver looks up the causal response appropriate for each possible configuration of information. This model predicts that RT should be not at all dependent upon the response given or else (in the variant of Orvis, Cunningham, & Kelley) that single-component responses should be quickest.

Subtraction and Salience

The subtraction model of attributional processing faces a problem that has not been discussed yet, namely the origin of the specific causal elements included in the initial tentative response. Other models, for example the additive model, do not face this problem: for them, a causal component (e.g., person or circumstances) to be added to the tentative response is suggested by a consideration of available information (e.g., consensus or consistency) about the event under scrutiny. But the subtractive model holds that people start with a list of causal elements *prior* to examining the relevant information. Where do these causal possibilities come from? The reason this issue has not been discussed to this point is that its solution in the context of the McArthur experiment is obvious: subjects use the causal possibilities suggested by the dependent measure. If the subtractive model is to describe attributional processing outside this context, though, some other mechanism must be involved.

In fact, the literature contains evidence for several possible mechanisms. One is salience. A model of attribution proposed by Pryor and Kriss (1977) and Taylor and Fiske (1978) holds that perceivers seize upon a single sufficient cause that is salient or available to them and report it as their attribution. The current model of causal subtraction would go beyond that claim to hold that *salient causes are candidates for the initial list of causes*. They are then processed subtractively and if not ruled out are reported as the person's attribution. The subtraction model thus predicts the salience phenomena that have been empirically obtained by the above-mentioned researchers and others, since salient causes will be considered as candidate causes and will often be given as an attribution. The proposal advanced here, however, goes beyond prior proposals to put the role of salience into a broader context of attributional information processing.

A second possible mechanism is scripts. If the action to be explained is part of an expected sequence of events, then the script (Schank & Abelson, 1977) of which it is part may suggest one or more plausible candidate causes. For example, if the waiter comes to one's table in a restaurant, one can tentatively guess that he may be bringing a menu, preparing to take one's order, and so forth. Again, these causes should then be subtractively processed. Thus, *scripted causes are also candidates for the initial list*. There are other possible sources of causes as well; for example, a person may simply (for idiosyncratic reasons) enter a situation with some specific expectation as to the nature of the causal factors operating there.

In any case, the subtraction model's difficulty seems solvable. Even outside the experimental context, sources of candidate causal factors (salience, scripts, or expectations) that enable the person to put together an initial list of one or more tentative causes are frequently available. The model holds that this initial list is then processed by attempting to rule out causes. When this has been done to the perceiver's satisfaction (the criterion may be influenced by demands to be careful, anxiety, or time pressure, etc.), the perceiver reports a cause. It is not yet clear what will happen if the perceiver succeeds in ruling out all candidate causes from the list. Presumably a new list will be put together and subjected to the same process of subtraction, and this should be time-consuming.

Conclusions

The data reported here are interpreted by proposing a two-stage model of the cognitive processing elicited by the experimental task, encoding or comprehending the stimulus text and attributional processing itself. Examina-

tion of the relationship between RT and the content of the response led to the proposal that perceivers assign a cause by subtracting causal components after beginning by considering as candidates the full set of three components. The subtractive model was shown to be consistent with salience effects on attributions, since perceptual salience can suggest candidate causes for consideration.

The methods applied in this paper have been much used in cognitive psychology but have as yet found little application in social psychology. The work of Kintsch (1974; Kintsch & van Dijk, 1978) and others on text comprehension should be referred to for clues as to how social psychologists might increase their knowledge of the first stage, the comprehending or encoding of events for attribution. Response time methods can be extended to cover attributional processing in other types of situation and with different materials and response formats, allowing tests of the idea that the basic subtractive nature of the attribution process may be a stable, general feature.

The Effects of Self-Esteem, Success–Failure, and Self-Consciousness on Task Performance

Joel Brockner
State University of New York College at Brockport

Previous research has demonstrated that the task performance of low self-esteem individuals (low SEs) suffers in the presence of self-focusing stimuli (e.g., a mirror). The present study was designed to determine if such stimuli must inevitably have adverse effects on low SEs. It was reasoned that if low SEs were provided with success feedback from a previous task, then the nature of their self-consciousness would be altered on a subsequent task. Specifically, low SEs should attend more to positive and less anxiety-provoking aspects of themselves than would low SEs who received failure feedback from the previous task. Under the former condition, the low SEs' subsequent task performance was expected to improve. For high self-esteem individuals (high SEs), who typically perform well, previous success–failure feedback was expected to have little effect on subsequent performance. In a three-factor design, subjects high and low in chronic self-esteem received false success or failure feedback from a previous task and completed a concept formation task in either the presence or the absence of a mirror. Whereas high SEs performed equally well following success or failure, low SEs in the success condition performed significantly better than low SEs in the failure condition (and just as well as high self-esteem–success participants). This Self-Esteem × Prior Feedback interaction was significant in the presence of the mirror, but not in its absence. In the absence of the mirror, however, this interaction was observed for subjects who were high in dispositional self-consciousness, but not for those who were low. Practical and theoretical implications of these findings are discussed.

Clinical practitioners and researchers have long been concerned with ways to enhance the self-evaluations of individuals suffering from low self-esteem (SE). Unfortunately, this task has proven quite difficult, as low self-esteem people (low SEs) seem to be trapped in a "vicious cycle" of negativity. For example, many investigators (Hamachek, 1971; Shrauger, 1972) have reported that low SEs do significantly worse in achievement settings (i.e., situations that have evaluative implications for one's SE) than do high self-esteem subjects (high SEs). Poor performance, in turn, would seem to set the stage for continued self-criticism and low SE.

What are the precise causes of the low SEs' often poor task performances? A recent series of experiments (Brockner, 1979; Brockner & Hulton, 1978) suggested that one important factor was the low SEs' focus of attention during task performance. In several studies the performance of the low SEs (but not of the high SEs) was quite malleable across conditions, depending on the manipulation of their attentional focus. Thus low SEs did quite poorly in the presence of stimuli designed to increase self-focused attention (i.e., an audience, a mirror, and a video camera). However, the low SEs' performance was also enhanced considerably by

The author thanks Topic Editor Charles S. Carver, John Eckenrode, Marc Riess, Larry Wallnau, Robert Wyer, and two anonymous reviewers for their astute comments on an earlier version of the manuscript. He is also indebted to Michelle Beirne, Kathy Dems, Bruce Machlica, and Ken Watson for their very able assistance in the collection of the data.

a set of instructions intended to increase task-focused and decrease self-focused attention. These latter data have implications for breaking the vicious cycle of low SE. It seems entirely possible that if low SEs repeatedly improve their task performance their self-opinions may begin to become more positive.

Low SE, Focus of Attention, Anxiety, and Performance

Brockner (1979) suggested that the attentional focus manipulations produced differential levels of anxiety for low SEs that in turn could have mediated task performance. That is, the self-focusing stimuli appeared to make the low SEs more anxious, whereas the task-focusing instructions, by reducing self-consciousness, were thought to make them less anxious. Brockner also presented evidence consistent with the notion that anxiety and performance were inversely related—not surprising, given the fairly complex nature of the task (see Spence, Farber, & McFann, 1956).

If Brockner's (1979) analysis is correct (i.e., if the attentional manipulations influenced the low SEs' anxiety, and if their anxiety mediated performance), then several questions confront researchers who wish to discover methods to improve the task performance of low SEs. Perhaps most important, does self-focused attention always covary with anxiety for low SEs? Stated another way, must low SEs' anxiety level always increase in the presence of self-focusing stimuli? If self-focused attention and anxiety always covary for low SEs, then self-focusing stimuli should inevitably produce decrements for low SEs on tasks in which anxiety is known to impair performance. However, if low SEs' self-focused attention and perceived anxiety need not covary, then it may be possible for low SEs to perform well on such tasks, even in the presence of self-focusing stimuli. In fact, Brockner (1979) observed that the low SEs' performance does not always have to suffer in the presence of self-focusing stimuli. In one study low SEs were placed in front of a mirror *and were also* instructed to concentrate on the task. It was found that these subjects made significantly fewer errors than low SEs who performed the task in front of a mirror but were not told to focus on the task. It was suggested that by concentrating on the task, the former group's level of self-focus, and therefore anxiety, was reduced.

To reduce the anxiety of low SEs, is it always necessary to *reduce* their level of self-focused attention? Or is it also possible to minimize their anxiety (and thereby enhance performance) by changing *the self-aspect that is focused on* when attention is self-directed? Both Duval and Wicklund (1972) and Wicklund (1975) have suggested that the affective nature of self-focused attention largely depends upon what happened to the individual prior to his being made self-aware. Therefore, under certain conditions, self-focused attention can be affectively pleasant; for example, if the individual received positive feedback on some personality dimension, then self-focused attention actually enhanced positive affect (Ickes, Wicklund, & Ferris, 1973). Moreover, recent research by Scheier and Carver (1977) convincingly demonstrated that self-focused attention can intensify any emotional experience, regardless of its affective nature.

Present Study

In the present study, subjects high and low in chronic self-esteem first received either success or failure feedback on a social insight test and then completed a concept formation task in either the presence or absence of a self-focusing stimulus. Results obtained by Ickes et al. (1973) and Scheier and Carver (1977) suggest that low SEs who are provided with success feedback and then made self-aware should experience self-focus characterized by more positive and/or fewer anxiety-provoking thoughts. Under these circumstances low SEs should perform well on the concept formation task. Alternatively, if they are provided with failure feedback, low SEs will probably experience negative affect. The self-focusing stimulus accompanying the concept formation task should then cause an increase in anxiety awareness. Accordingly, low SEs would be expected to do quite poorly on the task in this condition.

On the basis of previous research, it was expected that the affective state of the high SEs would be less influenced by the success–failure feedback than the affective state of the lows. Given that high SEs are generally already low in anxiety (Crandall, 1973), the success feedback should not have such pronounced effects. Moreover, research by Shrauger and Rosenberg (1970) strongly suggests that the high SEs' greater ego strength would allow them to withstand the potentially anxiety-provoking effects of the failure feedback. High SEs, in addition to being less affectively influenced by success–failure feedback, also report lower levels of self-focused attention in the presence of self-focusing stimuli (Brockner, 1979; Brockner & Hulton, 1978). For these two reasons the self-focusing stimulus should not have the amplifying effects on affect and performance that it is expected to have on the low SEs. Rather, high SEs should perform well in the self-focus condition after either success or failure.

Because the low SEs' affective states were expected to be less polarized in the absence of self-focusing, the condition differences in performance in the no self-focus conditions, although similar to those expected in the self-focus conditions, may not attain statistical significance.

In sum, the present study consisted of a three-factor (SE × Prior Feedback × Attentional Focus) design. A SE × Prior Feedback interaction was predicted, such that (a) low SEs would perform worse in the failure than in the success condition, with no corresponding difference for high SEs, and (b) low SEs would perform worse than high SEs in the failure condition, but just as well as high SEs in the success condition. Moreover, this interaction effect was only clearly expected to be significant in the self-focus condition.

Subjects also completed a measure of dispositional self-consciousness (the private self-consciousness scale of Fenigstein, Scheier, & Buss, 1975) prior to performing the concept formation task. Previous research has shown that this individual difference variable, like situational manipulations of self-focused attention, is directly related to awareness of one's emotional state (Scheier, 1976; Scheier & Carver, 1977). Furthermore, it has been suggested that personality variables are most likely to be related to behavior when relevant situational stimuli are absent or ambiguous (Mischel, 1973). Therefore, it was expected that in the no self-focus condition, (a) the performance of subjects high in private self-consciousness would parallel the behavior already predicted for subjects in the self-focus condition, and (b) subjects low in private self-consciousness would be less apt to demonstrate the basic SE × Prior Feedback interaction effect hypothesized above.

Method

Participants

The 100 undergraduate participants were volunteers recruited on the campus of the SUNY College at Brockport. The data of 7 subjects who were suspicious about the experimental procedure and 3 who did not understand the instructions were not included.[1] The final sample consisted of 60 females and 30 males, who were randomly assigned to conditions. Subjects' SE and self-consciousness were assessed by scales completed immediately prior to the experiment.

Self-esteem. The self-esteem scale was identical to the one used by Brockner (1979) and Shrauger (1972). The scale measures the subjects' perceived competence across 16 various situations (academic, athletic, and social). Subjects were asked to indicate the percentage of time a particular positive behavior or outcome applied to them. The average score for all 16 items was computed for each subject, such that higher scores represented higher SE. Subjects were classified as high or low SEs on the basis of a median split.

Self-consciousness. Subjects also indicated on 6-point scales how much each of the private self-consciousness statements of Fenigstein et al. (1975) was characteristic of them. The scores for each subject were summed over the 10 items, with higher scores representing greater self-consciousness. A median split was employed to classify subjects as high or low in private self-consciousness. SE and private self-consciousness were not related, $r(88) = .06$.

Procedure

All participants were run one at a time. Upon entering the laboratory they were greeted by a

[1] Interestingly, all of the discounted subjects for whom there were data ($N = 7$) were in the failure condition. More will be said about their performance on the concept formation task in the Results section.

female experimenter, led to a cubicle, and told that this "problem-solving" experiment would consist of several parts. First, subjects were asked to complete the SE and self-consciousness inventories. Afterward they responded to the Chapin Social Insight Test (Gough, 1968).

Social insight test. For each of these 10 problems, subjects read a short paragraph describing a social situation. They then had to choose one of four alternatives that they thought was the best explanation of the behavior of the individuals described in the paragraph. Subjects were told that the test measures the ability to "see into" social situations and, to heighten their psychological involvement, that social insight is "correlated with a person's capacity to show empathy for others, to predict others' responses in social situations, and it relates to a person's general understanding of human nature. After completing the test you will be informed of how well you did on it." The test took 10–15 minutes to complete.

When subjects finished the test, the experimenter excused herself while she went to "score" their performance. Returning about 3 minutes later, she administered the false feedback. In the success condition subjects were told that they scored in the 90th percentile of a group "consisting of you and your peers." In the failure condition subjects were told that they had scored in the bottom 20% of their peer group. After leaving the subjects for 1 minute so that they would absorb the feedback, the experimenter returned and asked them to complete a manipulation check questionnaire.

Subjects were then led across the hall to "complete the last part of the experiment." In this second room, a male experimenter blind to the subjects' feedback condition and SE and self-consciousness scores seated the subjects at a desk where they found the concept formation task (described immediately below) and the accompanying instructions. Subjects read the instructions to themselves while the experimenter simultaneously read them aloud. Subjects were also given a practice trial to familiarize them further with the task. After the practice trial was completed, subjects estimated on a 41-point scale how well they expected to perform at the task (endpoints were "very poorly" [1] and "very well" [41]). These data were collected for exploratory purposes but will become relevant in the discussion of the results.

Concept formation task. The task was identical to the one employed by Brockner (1979; Brockner & Hulton, 1978). Specifically, 32 squares were attached to a $14 \times 25 \times .25$ inch ($36 \times 64 \times .6$ cm) wooden board. Each square had five characteristics: number, size, color, shape, and position. Beneath each square a small hole had been drilled in the wooden board. The subject was told that the concept consisted of one, two, or three characteristics. The experimenter selected a square that was an example of the correct concept. The subjects' task was to determine the concept by lifting up other squares, one at a time. If the square was an example of the correct concept, the word YES was written on a piece of oak tag below the board. If the square was not an example of the concept the word NO was written below. When subjects believed that they had ascertained the correct concept, they wrote it on a slip of paper provided to them. At no time were subjects ever informed of the accuracy of their responses. Subjects were told that although "we are interested in the speed and accuracy with which you determine the concepts, it is more important to be accurate."

Attentional focus. The manipulation of attentional focus was introduced just before subjects began the concept formation task. In the self-focus condition subjects were told:

> One more point. Since we are interested in how people go about forming concepts, the experimenter will be watching you as you are working on the task. Also, a mirror will be placed in front of you, making it easier for the experimenter to observe your behavior more closely.

With that, the experimenter placed a large mirror (24×36 inches—61×91 cm), which had hitherto been unexposed, directly in front of the subject. A large mirror was employed in order to strengthen its self-focusing effect. That is, subjects could see not only themselves but also the experimenter observing them as they worked on the task. In the no self-focus condition the mirror manipulation was never introduced.

In all conditions subjects then began to work on the task, which was comprised of seven trials. The experimenter, seated adjacent to the subjects, recorded the amount of time taken and the number of squares looked at for each trial. When the seventh trial was completed, subjects answered a postexperimental questionnaire. In addition to indicating the nature of their attentional focus and the anxiety they felt while completing the task, subjects wrote their hypotheses and suspicions about the study. Finally, because of the potentially sensitive nature of the subject matter under study, all participants were carefully debriefed.

Results

Performance [2]

Errors of both commission and omission were summed over the seven trials to deter-

[2] Only the error data will be reported. Other qualitative performance measures included the time taken to complete the trials and the number of squares looked at before subjects made their responses. Consistent with previous research (Brockner, 1979; Shrauger, 1972), there were no condition differences on the time measure. The only effect to emerge on the other measure was the Feedback × Attentional Focus interaction ($p < .05$). This effect will not be considered further because it is not consistent with any other findings in this study, and no previous researchers have ever found condition differences on this measure.

mine task performance. A preliminary t test revealed no effect for sex of subject, $t < 1$. Therefore, the data were analyzed with a three-factor unweighted-means analysis of variance. The only effect to attain significance was the SE × Prior Feedback interaction, $F(1, 82) = 4.22$, $p < .05$. Simple effects elucidated the nature of this effect. Specifically, low SEs performed worse than high SEs in the failure condition, $F(1, 82) = 7.39$, $p < .01$, but not in the success condition ($F < 1$).[3] Moreover, low SEs made significantly more errors in the failure than in the success condition, $F(1, 82) = 6.81$, $p < .02$, whereas high SEs were unaffected by the feedback manipulation ($F < 1$).

While the triple interaction did not achieve significance, the means in Table 1 suggest that the significant effects reported above were largely attributable to the results obtained in the self-focus condition. Indeed, planned comparisons (i.e., simple interaction effect analyses) demonstrated that the SE × Feedback interaction was significant in the self-focus, $F(1, 82) = 4.55$, $p < .05$, but not in the no self-focus condition ($F < 1$).[4] Additional simple effect analyses revealed that the only instance in which low SEs made significantly more errors than high SEs was in the failure–self-focus condition, $F(1, 82) = 10.25$, $p < .005$, whereas the only time significantly more errors were made in the failure than in the success condition was in the low SE – self-focus condition, $F(1, 82) = 4.02$, $p < .05$.

Table 1
Task Performance by Condition

Attentional focus/self-esteem	Prior feedback: Success n	M	SD	Failure n	M	SD
Self-focus						
High	11	3.64	2.34	14	2.21	2.36
Low	10	3.90	3.54	11	6.73	4.88
No self-focus						
High	14	3.36	2.13	10	4.20	4.21
Low	11	2.73	3.35	9	5.11	3.37

Note. Performance was measured by errors. Scores ranged from 0 to 18. Thus the higher the score, the poorer the performance.

Table 2
Task Performance by Condition, Including Private Self-Consciousness

Private self-consciousness/ self-esteem	Prior feedback: Success n	M	SD	Failure n	M	SD
Self-focus						
High/high	5	4.40	2.07	10	1.70	1.57
High/low	5	6.40	3.13	5	5.20	4.32
Low/high	6	3.00	2.53	4	3.50	3.70
Low/low	5	1.40	1.67	6	8.00	5.33
No self-focus						
High/high	6	5.00	1.55	4	3.25	2.36
High/low	6	2.17	3.06	4	7.50	3.42
Low/high	8	2.13	1.64	6	4.83	5.23
Low/low	5	3.40	3.19	5	3.20	1.92

Note. Performance was measured by errors. Scores ranged from 0 to 18. The higher the score, the poorer the performance.

Self-consciousness analysis. To test for the main and interaction effects involving the dispositional self-consciousness variable, a four-factor (Self-Consciousness × SE × Feedback × Attentional Focus) unweighted-means analysis of variance was performed. The only significant effect to emerge, in addition to the already reported SE × Feedback interaction,

[3] The data of seven subjects in the failure condition were discarded because of their suspicions about the validity of the social insight test. Perhaps because the impact of the failure feedback was lessened for these subjects, they tended to make very few errors on the task. Nevertheless, the four subjects who would have been low SEs still made more errors ($M = 2.50$) than the three would-be high SEs ($M = 1.33$).

[4] Previous researchers (Brockner, 1979; Brockner & Hulton, 1978; Shrauger, 1972) have found SE differences on this task in the presence, but not in the absence, of self-focusing stimuli. Furthermore, the a priori hypothesis of the present study, on theoretical grounds, was that the SE × Feedback interaction would be significant in the self-focus but not necessarily in the no self-focus condition. Winer (1971) clearly states that it is legitimate to compare specific means, if the comparisons were planned prior to the inspection of the data. The appropriate planned comparisons, therefore, were the simple interaction effect analyses in the self-focus and no self-focus conditions.

was the four-way interaction, $F(1, 74) = 7.25$, $p < .01$. By inspecting Table 2, one finds that there were nonsignificant performance differences between SE groups in the success conditions. In the failure conditions high SEs performed far better than low SEs, except in the absence of a source of self-focused attention (i.e., the no self-focus – low self-consciousness condition). Although the means in the self-focus condition suggest that the SE × Prior Feedback interaction was stronger for subjects low, rather than high, in dispositional self-consciousness, the simple triple interaction effect (comparing the SE × Feedback interaction for high vs. low self-conscious subjects) revealed that this difference was not significant, $F(1, 74) = 1.44$. In the no self-focus condition, high self-conscious subjects exhibited a similar SE × Feedback interaction shown by all subjects in the self-focus condition, whereas low self-conscious subjects did not. Indeed, the simple triple interaction effect did attain significance in the no self-focus condition, $F(1, 74) = 6.79$, $p < .02$. In short, in the no self-focus condition, subjects high in self-consciousness responded (a) like subjects in the self-focus condition and (b) unlike subjects low in self-consciousness. Stating the latter effect more generally, the personality variable only had an effect in the absence of the mirror, that is, the relevant situational stimulus (Mischel, 1973).[5]

Manipulation Checks

Prior feedback. After receiving their feedback but before starting to work on the concept formation task, subjects completed two 41-point scales measuring their affective states (Question 1: At this point, how socially insightful do you think you are? Anchor points: "not at all" [1] and "very" [41]; Question 2: How would you describe your current mood state? Anchor points: "very bad mood" [1] and "very good mood" [41]). Since the two items correlated significantly, $r(88) = .44$, $p < .01$, an affect index was computed for each subject by summing the scores. Because these measures were collected before the attentional focus variable had been manipulated, a two-factor unweighted-means analysis of variance was performed on the index. The analysis revealed a significant interaction effect, $F(1, 86) = 7.10$, $p < .01$. Low SEs expressed more positive affect in the success than in the failure condition, $F(1, 86) = 24.27$, $p < .001$, whereas high SEs did not, $F(1, 86) = 1.34$. Moreover, high SEs were only more positive than low SEs in the failure condition, $F(1, 86) = 12.10$, $p < .005$.

Attentional focus. Two 41-point self-report items were employed to measure the amount of positive and negative thoughts subjects were having about themselves while working on the task. Question 1 measured positive (e.g., feeling confident) and Question 2 negative (e.g., thinking I was doing poorly) self-evaluative thoughts. Three-factor unweighted-means analyses revealed a SE × Feedback interaction on the first question, $F(1, 82) = 3.98$, $p < .05$. Specifically, it was only in the failure condition that high SEs were having more positive thoughts than low SEs. On the second question the means were in the opposite direction, but all effects were nonsignificant. Thus, it was only in the failure condition that low SEs tended to have more negative thoughts than high SEs.

Anxiety. Subjects were also asked, "*While you were completing the task,* (a) how anxious did you feel, and (b) how much did the experimenter's presence bother you?" Since the two items were well correlated, $r(87)$[6] $= .42$, $p < .01$, an anxiety index was formed by summing each subject's scores. The analysis of variance revealed a significant SE main effect, $F(1, 81) = 4.85$, $p < .05$, with low SEs more anxious than high SEs, and a mar-

---

[5] Subjects were also measured on the other two subscales of the self-consciousness scale of Fenigstein et al. (1975), that is, public self-consciousness and social anxiety. The four-factor analysis involving the public self-consciousness variable yielded a marginally significant four-way interaction ($p < .10$), the nature of which was similar to that observed on the private self-consciousness analysis. The social anxiety analysis was not performed because an unbalanced distribution of that variable caused one of the conditions to contain only one subject.

[6] One subject inadvertently failed to complete the first anxiety measure. Thus, the degree of freedom is 87 rather than 88.

ginal SE × Feedback interaction, $F(1, 81) = 2.76$, $p < .10$. Interestingly, the mean condition differences on the index were remarkably similar to the performance data reported in Table 1. Although the triple interaction was not significant, simple interaction effect analyses showed that the SE × Prior Feedback interaction effect was significant in the self-focus condition, $F(1, 81) = 4.90$, $p < .05$, but not in the no self-focus condition ($F < 1$). Low SEs were only significantly more anxious than high SEs in the failure–self-focus condition, $F(1, 81) = 8.64$, $p < .01$, and the only instance in which failure subjects were more anxious than success subjects was the low SE – self-focus condition, $F(1, 81) = 4.90$, $p < .05$.

Correlational Data

The pattern of the SE × Feedback interaction was similar on measures of self-evaluative thoughts, anxiety, and task performance. Further suggestive evidence that task performance was mediated by subjects' self-evaluative thoughts and anxiety levels stems from a series of correlations. Specifically, subjects' positive thoughts were inversely related, $r(88) = -.42$, $p < .01$, and their negative thoughts were directly related, $r(88) = .36$, $p < .01$, to the number of errors they made. There was also a positive correlation between subjects' anxiety index scores and the number of errors they committed, $r(87) = .33$, $p < .01$.

Discussion

In sum, the major hypotheses of the study were supported. It was predicted that the feedback would cause low (but not high) SEs to attend to different aspects of themselves, such that the self-evaluative statements made by low SEs would be more anxiety-provoking following failure than following success. Self-focused attention was expected to intensify anxiety awareness, which in turn was thought to mediate task performance. Indeed, the task performance results showed that low SEs made more errors than high SEs following failure, as long as there was some source of self-focused attention (i.e., the situationally produced self-awareness or subjects' own tendencies towards self-consciousness). Following success, low SEs performed just as well as high SEs in all conditions.

The fact that low SEs performed better following success has implications for breaking the vicious cycle of low self-esteem. That is, previous investigators (Brockner, 1979; Brockner & Hulton, 1978; Shrauger, 1972) have demonstrated that low SEs' performance deteriorates in the presence of self-focusing stimuli. The present results suggest, however, that by reducing the low SEs' anxiety before making them self-aware, one can block the negative effects of the self-focusing stimulus on their performance. Of course, in the absence of a no feedback – self-focus condition, it is not known whether the success feedback reduced the low SEs' anxiety and enhanced their performance, whether the failure further heightened anxiety and impaired performance, or whether both occurred. However, in what would amount to a relevant no feedback – self-focus condition, Brockner (1979) found that high SEs made 2.50 errors, whereas the mean score for low SEs was 7.22. These data are very close to the means observed in the failure – self-focus condition in the present study. Thus, for low SEs in the self-focus conditions, it would appear that the success feedback reduced anxiety and enhanced performance, whereas the failure had only slight effects.

Alternative interpretation. It could be argued that the mirror produced its effects by serving as a source of general arousal. More specifically, consider the following logical sequence. Feedback may have manipulated the direction of attentional focus experienced by low SEs, so that they were more task-focused and less self-focused following success than failure. Accordingly, their performance should be better following success. The mirror may then have acted as an arousal source, enhancing performance differences by further restricting the range of cues to which subjects attended (Easterbrook, 1959). That is, restriction of cues among task-focused subjects would have increased task focus; cue restriction among self-focused subjects would have further decreased task focus. How might the mirror's

presence have enhanced arousal? Given the instructions that accompanied the introduction of the mirror ("so that the experimenter can watch you more closely") and the fact that subjects could see the exprimenter observing them in the mirror, the perceived importance and/or evaluative nature of the task may have been greater in the self-focus than in the no self-focus condition.

Although this alternative explanation warrants consideration, there is evidence against it. For example, if the mirror was a source of general arousal because it caused subjects to attribute more significance to the task, then they should have assigned greater importance to the task in self-focus than no self-focus conditions. Although no measures of perceived task importance were collected in this study, Brockner (1979) did measure "the importance of doing well at this task" as a function of SE and the presence of a mirror and video camera (using the same justification to introduce the self-focusing stimuli that was employed in the present study). There was no tendency for subjects (including low SEs) to attribute more importance to the task in the presence of the self-focusing stimuli.

In addition, it has been demonstrated that private self-consciousness does not correlate with individual difference measures of arousal/emotionality (e.g., general emotionality, test anxiety, social anxiety; Scheier & Carver, 1977). In examining the performance data of high private self-conscious subjects in the no self-focus condition (see Table 2), one finds that the SE × Feedback interaction was parallel to the one observed for *all* subjects who were exposed to the mirror. In attempting to account for such parallel effects of manipulated and dispositional self-attention, Scheier and Carver have suggested that "an interpretation based on arousal may provide a viable explanation for the effects of a mirror, but it cannot account for the effects of private self-consciousness. An interpretation based on self-focused attention can explain both the effects of a mirror and the effects of private self-consciousness. Thus, although different interpretations can be used to explain the effects of a mirror and private self-consciousness separately, at this time the self-awareness interpretation appears more reasonable, comprehensive, and parsimonious" (Scheier & Carver, 1977, p. 634).

A similar line of reasoning may be used to suggest that the mirror did not cause increased evaluation apprehension. That is, if the mirror enhanced evaluation apprehension, then subjects in the no self-focus condition who are more sensitive to the evaluation process (those high in social anxiety; Turner, 1977) should have performed as did those in the self-focus condition. As stated previously, the social anxiety analysis was not conducted because one of the cells (in the no self-focus – low social anxiety condition) contained only one subject. However, there were enough subjects in the no self-focus – high social anxiety condition to test this hypothesis. Interestingly, the results did not at all resemble the SE × Feedback interaction obtained in the self-focus condition. Rather, there was a slight tendency for both high and low SEs to make more errors following failure.

Self-Attention and Behavioral Self-Regulation

The present data are generally consistent with Carver's (1979) analysis of the consequences of self-directed attention. In essence, Carver suggests that when subjects are self-aware they will be more motivated to conform to the salient behavioral standard in a situation (e.g., to solve the concept formation task successfully). If arousal cues are not introduced, the subject should complete the task successfully. If fear or anxiety arousal cues become salient, however, the subject's task performance will be interrupted. At this point the individual will assess his/her likelihood of being able to complete the task. If the subject's expectations are positive, he/she will vigorously reattempt to match behavior to the standard. Subjects who feel unable to complete the task will respond with passivity and withdrawal.

To test this model, Carver, Blaney, and Scheier (1979a, 1979b) have presented subjects with fear or anxiety-provoking situations and have measured task persistence/performance. The results of these studies have generally supported the model: positive expect-

ancy subjects exhibit greater persistence/performance than negative expectancy participants, but only when self-focused attention is high.

One of the experiments of Carver et al. (1979b) is conceptually quite similar to part of the present design. In that study, all subjects were provided with failure feedback. Persistence at a subsequent task was measured as a joint function of self-awareness and expectancy for success at that second task. In the present study, some subjects were given failure feedback and then had to perform the concept formation task with no manipulation of expectancy. High SEs performed better than low SEs in the present research when attention was self-focused, but not when self-focus was lower. These results parallel those of Carver et al. if it can be assumed that (a) task persistence is related to task performance and (b) SE is positively related to expectancy for success at the concept formation task. The first assumption seems straightforward, and the second one was empirically supported in the present study. High SEs *did* expect to perform better than low SEs, $F(1, 86) = 6.77$, $p < .025$, particularly in the failure condition, $F(1, 86) = 5.80$, $p < .025$.

These performance data not only confirm those obtained by Carver et al. (1979a, 1979b), but they provide converging support for Carver's (1979) theoretical model. That is, to demonstrate that self-focusing is a necessary component of the model, Carver et al. employed situational manipulations of self-focused attention. In the present study, the fact that only subjects high in dispositional self-consciousness in the no self-focus condition performed as did those in the self-focus condition further attests to the importance of self-focused attention.

The lack of SE differences in performance in the success–self-focus conditions can also be explained by self-regulation theory. First, given the previous success, rather than failure, feedback, subjects' arousal level while completing the task may not have been high. Hence they would not necessarily be expected to interrupt task performance to assess the likelihood of successful task completion. Moreover, even if subjects did assess these expectancies, no SE differences in performance would be predicted, as high and low SEs did not reliably differ in their expectations for performance in the success condition, $F(1, 86) = 1.62$.

Conclusions

The task performance findings in this study are a logical extension of those observed in previous research (Brockner, 1979). In the earlier study, to enhance their task performance in the presence of a self-focusing stimulus, low SEs were told to concentrate diligently on the task. Thus, the previous study adopted a quantitative approach to combating self-focused attention for low SEs, in that the task-focus instructions were designed to reduce *the degree of* the low SEs' self-focusing. The present study entailed a more qualitative strategy to offset the negative effects on performance of the low SEs' self-focused attention. Rather than reduce the degree of their self-focusing, an attempt was made to change *the nature of* the low SEs' self-focused attention by providing them with success feedback from a previous task. This strategy also proved to be effective, as the low SEs' task performance was no longer impaired in the presence of the self-focusing stimulus. These performance data are consistent with and serve to extend recent theorizing about the consequences of self-directed attention.

A New Round Robin Analysis of Variance for Social Interaction Data

Rebecca M. Warner

Michael Stoto
Harvard University

Experimental social psychology has dealt primarily with situations that are not true social interactions; in a typical study, a subject responds to a fixed, artificial social stimulus such as a photograph, written description, or performance by a confederate. Although these artificial social stimuli provide experimental control over independent variables and can be analyzed using the types of statistical models originally developed for nonsocial experimental research, they provide little or no information about the interactive aspects of social behavior—the reciprocity or mutual contingency of the behavior of interaction partners. This paper describes a nonexperimental design specifically tailored to social interaction data that provides more information about individual differences and social influence in social interactions: a round robin design in which each person interacts with every other person. After a brief review of available models, a new and more general model for the analysis of social interaction data is presented, with an empirical demonstration using vocal activity data.

Experimental social psychology has often been limited to the study of artificial, one-sided social situations in which the subject responds to some fixed social stimulus created by the experimenter; this has been the case even in research on person perception and interpersonal attraction, where it is especially apparent that the behaviors and attitudes of persons are mutually contingent (i.e., A's liking for B affects B's liking for A, and vice versa). In research on subject reactions to fixed stimuli (rather than the reactions to other persons in the context of naturally occurring social interactions), information about the reciprocity of social behaviors is lost. Moreover, the use of standardized, artificial stimuli often precludes having stimuli that are representative of typical interactions. Thus, the generalizability of such studies may be rather limited.

A round robin design is one in which all possible pairs of subjects from some set of subjects interact (like the pairings formed in a tennis tournament). This term was introduced by Gleason and Halperin (1975). For each person paired with every other person, an observation is made of some social behavior (speech pattern, rating, or degree of attraction). Thus the "treatments" to which each subject reacts are the behaviors of other subjects. This design provides two kinds of information about social behavior—first, information about individual differences among subjects (in speech patterns, ratings, or other behaviors); second, information about the mutual influence that interaction partners have on each other's behaviors (for instance, the tendency to reciprocate positive feelings or to match the durations of certain kinds of pauses in speech).

Before introducing a new round robin analysis of variance, two simpler designs for social interaction data will be briefly reviewed. Each of these designs provides partial information about social behavior, and the round robin design can be understood as a model

Development of this model was supported in part by National Science Foundation Grant BNS 77-03271, David A. Kenny, principal investigator. Additional funds were provided by the Livingston Fund Award (Harvard Medical School).

that integrates and elaborates on these two simpler designs.

Intraclass Correlation

A common nonexperimental design for social interaction research is one in which a number of different dyads are formed and each subject's behavior toward one randomly assigned partner is observed. An example is a study reported by Welkowitz, Cariffe, and Feldstein (1976) on the congruence of vocal activity (i.e., the tendency for conversation partners to match the mean durations of their switching pauses, the pauses that occur after one person has stopped speaking and before the other person begins to speak). For each subject there is one observation, the mean switching pause duration in seconds. The observations are arranged by dyads, as illustrated by the hypothetical data displayed in Table 1.

To determine the strength of the tendency for partners to match pause durations, it is necessary to look at the correlation between the two columns of data, but an ordinary correlation coefficient is inappropriate here because the data do not consist of ordered pairs, that is, the assignment of any particular observation to the first or second column is arbitrary. This type of layout also occurs in examining twin data, as in research on IQ; here also there is no basis for labeling one twin X and the other twin X'. For this type of data layout an intraclass correlation is required (Snedecor & Cochran, 1967, 294–296). The r intraclass is calculated slightly differently from the ordinary product-moment r; each pair of observations is counted twice when computing the covariance term in the numerator—once as X, X' and again as X', X. Instead of calculating the variances of the X and X' groups separately, the denominator consists of the variance of all the observations. The r intraclass is just the ratio of these two terms. The intraclass correlation provides information about the matching or reciprocity of behaviors between partners, but it ignores individual differences among persons.

Table 1
Hypothetical Data Layout for Intraclass Correlation of Switching Pause Durations

Dyad	X	X'
1	.7	.9
2	1.2	1.1
3	1.5	.8

Note. Each entry is a hypothetical mean switching pause duration (in seconds). The sequence can of course be extended for Dyads 4, 5, 6, and so forth. X = switching pause duration for one of the speakers; X' = switching pause duration for the other speaker.

Table 2
Hypothetical Data Layout for an Analysis of Variance Design: Mean Proportion of Time Spent Speaking by Doctors

	Patients	
Doctor	Quiet, depressed	Talkative, anxious
1	23.4	15.7
2	36.6	24.1
3	45.9	26.3

Note. Design used by Goldman-Eisler (1952).

Ordinary Two-Way Analysis of Variance

A second approach to the study of social interaction involves the partitioning of variances to look for individual subject differences. Individual persons (or groups of persons) are treated as levels of subject factors in an ordinary analysis of variance. When there is some asymmetry of roles (such as doctor/patient or interviewer/interviewee), the data are easily translated into a two-way analysis of variance. An example of this design is a study by Goldman-Eisler (1952); the hypothetical data in Table 2 represent the mean proportion of time each doctor spent talking when paired with individual patients of two different types. This design can be treated as a two-way analysis of variance, and comparisons can be made of the following: individual differences among doctors in talkativeness; differences in the activity levels elicited from doctors by the two different types of patients; and interactions between doctor and patient type.

This design does deal with individual differences (both in the types of social behavior

Table 3
Round Robin Data Layout

Subject	Subject 1	2	3	4
1	—	X_{121}	X_{131}	X_{141}
	·	X_{122}	X_{132}	X_{142}
	—	X_{123}	X_{133}	X_{143}
2	X_{211}	—	X_{231}	X_{241}
	X_{212}	·	X_{232}	X_{242}
	X_{213}	—	X_{233}	X_{243}
3	X_{311}	X_{321}	—	X_{341}
	X_{312}	X_{322}	·	X_{342}
	X_{313}	X_{323}	—	X_{343}
4	X_{411}	X_{421}	X_{431}	—
	X_{412}	X_{422}	X_{432}	·
	X_{413}	X_{423}	X_{433}	—

Note. X_{ijk} = a behavior of Person i toward Person j on Day k.

that individuals exhibit and in the types of social behavior that groups of patients elicit); but it is less well suited to the study of social interactions among peers (i.e., social interactions that do not have a role asymmetry that makes it easy to assign some individuals to the row factor and others to the column factor); furthermore, it provides no information about mutual influence of social behaviors.

Round Robin Analysis of Variance

Model Specification

Round robin designs make it possible to obtain both kinds of information about social interactions—individual differences and mutual contingency. Several round robin–type designs have been developed (Bechtel, 1971; Gleason & Halperin, 1975; Lev & Kinder, 1957); all of these designs are applicable to data layouts in which each subject is paired with every other subject, but they differ with respect to the assumptions that they have made about the kinds of nonindependence among observations. Since these models have developed as a special application of the paired-comparisons design in psychophysical research, some of the assumptions of these models are rather restrictive or in other respects not ideally suited for some of the special difficulties that arise in social psychological research. The reason for developing a new model is to tailor the round robin design more specifically to the problems of social interaction and to make available a model with less restrictive assumptions about the type of dependence among observations. Depending on the research problem, however, one of these previously suggested models may be more appropriate; accordingly, the specifications of these other models will be described briefly later in this paper to assist readers in choosing the best model.

Round robin designs arise frequently in small-groups research, where records are kept of the frequency or duration of various types of acts that each group member addresses to each other group member; in studies of person perception, where each person rates every other person in a group; and such data may be generated by creating all possible pairs from a small subject pool and studying their behavior in isolation or by collecting data in group settings.

Any social psychological dependent variable can be used: summary information on speech, gaze, or body movements; frequency counts of the number of acts (aggressive, altruistic, or other); ratings, perceptions, or self-report measures of utility—the amount of some resource (money, time, materials, or whatever) that each person gives to each other person.[1]

A round robin data layout is illustrated in Table 3, where X_{ijk} is an observation of some social behavior of Person i toward Person j on Day or Time k.

The diagonal cells are empty, since ordinarily a person cannot be paired with himself or herself, and the matrix is asymmetric, since the behavior of Person i toward j is ordinarily different from that of j to i, even though they may be highly correlated. With some modifications, this will be treated as an $n \times n \times r$ analysis of variance, where n is the number of subjects and r is the number of observations made on each dyad. This is a random effects

[1] Note two limitations on appropriate data for the round robin analysis of variance—there should not be many cells with zero entries (apart from the diagonal cells), and neither the row nor column sums should be constant, as would occur if each subject allocated limited resources among other subjects (such as rank-order preferences or limited amounts of money).

model, that is, the set of n subjects is considered to be a very small random sample from a very large population of subjects; subjects were not selected to represent levels of some dimension (such as dominance). By treating this as a random effects model, we achieve greater generality. Formally stated, the model is as follows:

$$X_{ijk} = \underset{\text{mu}}{\mu} + \underset{\text{alpha}_i}{\alpha_i} + \underset{\text{beta}_j}{\beta_j} + \underset{\text{gamma}_{ij}}{\gamma_{ij}} + \underset{\text{epsilon}_{ijk}}{\epsilon_{ijk}}.$$

The α_i term represents the contribution of Person i as an actor, a source of behaviors; for instance, in a study of the proportion of time spent speaking in conversations, α_i represents Person i's talkativeness. The β_j term represents Person j's effect as a partner (i.e., the amount of talk that Person j tends to elicit from people when he/she is their partner). Note that these effects can be logically distinguished, although in the case of vocal activity there is a negative correlation between the proportion of time a person tends to talk, and the proportion of time he/she allows other persons to talk when he/she is their partner. For some other social variables, there might conceivably be a positive or zero correlation between the subject-as-actor and subject-as-partner effects. The γ_{ij} term is an interaction effect, representing the special adjustment which Person i makes in level of talkativeness when paired with Person j. As usual, ϵ_{ijk} represents the error term, which picks up variability in behavior at different times.

Looking at the layout in Table 3 may clarify the distinction made between actor and partner effect. The ith row mean represents the average behavior of Person i toward $n - 1$ different partners; thus the row variance indicates whether there are clear-cut and consistent individual differences among persons when their behavior is observed with a number of different partners. The jth column mean represents the average of behaviors of persons who have Person j as a partner; thus the column variance indicates whether there are significant differences among individuals as partners (that is, as social stimuli to which other persons react). These two main effects, row (actor) and column (partner) are both subject variables, and they are in fact based on the same set of subjects; in developing our new round robin model, we will distinguish the actor and partner factors and allow these two factors to be either positively or negatively correlated. Among the other round robin designs, different approaches are used: Bechtel (1971) treats actor and partner factors separately and allows them to be positively correlated; Lev and Kinder (1957) treat actor and partner as separate factors and require that they be independent; Bechtel (1967) and Gleason and Halperin (1975) treat actor and partner as equivalent and combine them into a single subject factor.

This nonindependence between the row and column factor is just one of the special considerations that necessitate the development of a special analysis of variance model; another special problem is the nonindependence of partner behaviors that comes about because social behaviors are mutually contingent. This mutual contingency means that the behavior of j to i is correlated with the behavior of i to j; or, to put it another way, in the layout in Table 3, the cells across the diagonal from each other (the i,j and j,i pairs of cells) are correlated, either positively or negatively. Since this violates the ordinary analysis of variance assumptions, it requires special adaptations in the specification of the model and the derivation of expected mean squares.

Many of the basic assumptions about expectations are unchanged: The expectations of row, column, and interaction effects and the expectation of the error are still zero. Formally, $E(\alpha_i) = 0$, $E(\beta_j) = 0$, $E(\gamma_{ij}) = 0$, and $E(\epsilon_{ijk}) = 0$, for all i, j, and k $(j \neq i)$, where E is the expectation operator. The usual variance specifications are also made:

$$E(\alpha_i^2) = \sigma_\alpha^2; \quad E(\beta_j^2) = \sigma_\beta^2; \quad E(\gamma_{ij}^2) = \sigma_\gamma^2;$$

and

$$E(\epsilon_{ijk}^2) = \sigma_\epsilon^2, \quad \text{for all } i, j, \text{ and } k, \ (j \neq i).$$

The sources of nonindependence outlined earlier (the correlation between row and column factors and between pairs of cross-diagonal cells) must also be incorporated into the model specifications. The covariance between Person i's effect as an actor (α_i) and Person i's effect as a partner (β_i) is formally

Table 4
Summary of Round Robin Model Specifications

$$E(\alpha_i) = 0, \quad E(\alpha_i^2) = \sigma_\alpha^2 \quad \text{for all } i$$
$$E(\beta_j) = 0, \quad E(\beta_j^2) = \sigma_\beta^2 \quad \text{for all } j$$
$$E(\gamma_{ij}) = 0 \quad \text{for all } i \text{ and } j,\ j \neq i$$
$$E(\epsilon_{ijk}) = 0 \quad \text{for all } i,\ j, \text{ and } k$$

$$E(\alpha_i, \beta_j) = \begin{cases} \rho_1 \sigma_\alpha \sigma_\beta & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

$$E(\gamma_{ij}, \gamma_{i'j'}) = \begin{cases} \sigma_\gamma^2 & \text{if } i = i',\ j = j' \\ \rho_2 \sigma_\gamma^2 & \text{if } i' = j,\ j' = i \\ 0 & \text{otherwise} \end{cases}$$

$$E(\epsilon_{ijk}, \epsilon_{i'j'k'}) = \begin{cases} \sigma_\epsilon^2 & \text{if } i = i',\ j = j',\ k = k' \\ \rho_3 \sigma_\epsilon^2 & \text{if } i' = j,\ j' = i,\ k = k' \\ 0 & \text{otherwise} \end{cases}$$

stated as $E(\alpha_i, \beta_i) = \rho_1 \sigma_\alpha \sigma_\beta$, hereafter referred to as the row and column covariance.

The covariance between pairs of cross-diagonal cells is more complex, since it consists of two parts. First, it is reasonable to assume that there is some correlation between γ_{ij} and γ_{ji} (that is, between i's special adjustment to j and j's special adjustment to i). This nonzero covariance between the interaction effects within dyads is represented as $\rho_2 \sigma_\gamma^2$; formally, the nonindependence assumption requires that we specify $E(\gamma_{ij}, \gamma_{ji}) = \rho_2 \sigma_\gamma^2$. This term will be referred to as the cross-diagonal interaction covariance, and it will be interpreted as evidence for some kind of lasting reciprocity of behaviors within dyads. Furthermore, it is likely that the error terms for the behavior of social interaction partners on a particular day or time will also be correlated; formally, $E(\epsilon_{ijk}, \epsilon_{jik}) = \rho_3 \sigma_\epsilon^2$; this will be interpreted as evidence for a situation-specific reciprocity in partner behaviors. All other covariances are assumed to be zero; the model specifications outlined in this section are summarized in Table 4.

For some types of social interaction data, there may be a further source of nonindependence among observations; in person perception data, if Persons h and j discuss their perceptions of Person i, then the h, i and j, i ratings may be correlated. In the vocal activity data presented as an illustration in this paper, this additional source of nonindependence is assumed not to occur, and some care should be taken to minimize this type of nonindependence in designing studies that are to be analyzed using round robin designs.

Before outlining the calculations and parameter estimation procedures, we should note the alternative model specifications briefly described in Table 5; depending on the nature of the data, one of the previously developed models may provide more powerful means of analyzing some data. This new model has the least restrictive assumptions of any of these designs.

Calculation of Means and Mean Squares

The strategy adopted for the purpose of developing the new model was as follows: First, we set up formulae for the sample means and mean squares; next, taking into account the empty diagonal cells and the nonindependence assumptions included in the model specifications, we worked out the expected mean squares; finally, we used the expected mean square equations to solve for the variance components of the model (e.g., σ_α^2, σ_β^2, σ_γ^2) in terms of the sample mean squares. Significance testing on these variance components was done by jackknifing, since ordinary F ratios are not easily set up. After these procedures have been outlined in detail, the model will be demonstrated using vocal activity data.

The computation of sample means is straightforward; the only special consideration is the presence of empty cells in the diagonal.

Grand mean:

$$M_{...} = \frac{1}{rn(n-1)} \sum_i \sum_{j \neq i} \sum_k X_{ijk}.$$

Row mean:

$$M_{i..} = \frac{1}{r(n-1)} \sum_{j \neq i} \sum_k X_{ijk}.$$

Column mean:

$$M_{.j.} = \frac{1}{r(n-1)} \sum_{i \neq j} \sum_k X_{ijk}.$$

Cell mean:

$$M_{ij.} = \frac{1}{r} \sum_k X_{ijk}.$$

As usual, the estimate of the grand mean is $M_{...}$. Because of the empty diagonal cell, $M_{i..} - M_{...}$ is not an unbiased estimate of the row effect (α_i); the following argument will explain why the empty diagonal cells produce bias in the row means of this layout.

When you sum across row i, for instance, you get an average of Person i's behavior with $n - 1$ partners, not including self. This means that the estimate of Person i's talkativeness relative to the talkativeness of the other persons in the sample is biased, since Person i is not observed with the same set of partners that all the other persons had. Since we can get an estimate of Person i's effect as a partner (β_i), however, it is possible to correct for this "missing partner" bias. For instance, in the data on proportion of time spent speaking in conversations, any particular observation (X_{ij}) depends upon the talkativeness of i, the person being observed, and the amount of talk elicited by j, the partner. Typically, the amount of talk elicited by j depends on j's talkativeness. If Person i is the most talkative person in the sample, the the fact that i lacks himself or herself as a partner means the estimate of his/her talkativeness is slightly inflated, since he/she had the last talkative set of partners of any individual in the sample. An analogous argument holds for bias in the column means. The estimates for the row effects and the column effects are as follows:

$$\hat{\alpha}_i = \frac{(n-1)^2}{n(n-2)} M_{i\cdot\cdot} + \frac{(n-1)}{n(n-2)} M_{\cdot i\cdot} - \frac{(n-1)}{(n-2)} M_{\cdot\cdot\cdot},$$

$$\hat{\beta}_j = \frac{(n-1)^2}{n(n-2)} M_{\cdot j\cdot} + \frac{(n-1)}{n(n-2)} M_{j\cdot\cdot} - \frac{(n-1)}{(n-2)} M_{\cdot\cdot\cdot}.$$

These equations make sense in light of the previous discussion; to get an estimate of Person i's true row effect, it is necessary to correct for the "missing partner" bias by adjusting by some fraction of Person i's column mean. As usual, once the row and column effects are known, estimates of the interaction effects can be obtained by subtraction:

$$\hat{\gamma}_{ij} = M_{ij\cdot} - M_{\cdot\cdot\cdot} - \hat{\alpha}_i - \hat{\beta}_j.$$

The calculations for mean square row and mean square column are straightforward, but the coefficients are slightly different; note that the total number of observations in the design is $rn(n-1)$ and the number of observations in a row or column is $r(n-1)$.

$$MS_{\text{row}} = \frac{r(n-1)}{(n-1)} \sum_i (M_{i\cdot\cdot} - M_{\cdot\cdot\cdot})^2.$$

$$MS_{\text{column}} = \frac{r(n-1)}{(n-1)} \sum_j (M_{\cdot j\cdot} - M_{\cdot\cdot\cdot})^2.$$

Before going further, notice how the empty cells and the special nonindependence assumptions affect the variance components that are estimated by the row mean square. For $M_{i\cdot\cdot}$ and $M_{\cdot\cdot\cdot}$, we have:

$$M_{i\cdot\cdot} = \mu + \alpha_i - \frac{\beta_i}{(n-1)} + \bar{\gamma}_{i\cdot} + \bar{\epsilon}_{i\cdot\cdot}$$

$$M_{\cdot\cdot\cdot} = \mu + \bar{\alpha}_{\cdot} + \bar{\beta}_{\cdot} + \bar{\gamma}_{\cdot\cdot} + \bar{\epsilon}_{\cdot\cdot\cdot}$$

When these expressions are used to derive the expected mean square for row effect, the special assumptions incorporated into the model specifications mean that many cross-multiplication terms whose expected values would be zero in an ordinary analysis of variance now have nonzero expectations; for instance, since α_i is correlated with $\bar{\beta}_{\cdot}$, there will be a nonzero covariance term picked up when the α_i term in the equation for $M_{i\cdot\cdot}$ is multiplied by the $\bar{\beta}_{\cdot}$ term in the equation for $M_{\cdot\cdot\cdot}$ and their expectation is taken. The expected mean square for row in the round robin model includes the following terms.

$$EMS_{\text{row}} = r(n-1)\sigma_\alpha^2 + \frac{r}{(n-1)}\sigma_\beta^2 + r\sigma_\gamma^2 - 2r\rho_1\sigma_\alpha\sigma_\beta - \frac{r}{(n-1)}\rho_2\sigma_\gamma^2 + \sigma_\epsilon^2 - \frac{1}{n-1}\rho_3\sigma_\epsilon^2,$$

where $\rho_1\sigma_\alpha\sigma_\beta$ is the Row × Column covariance, $\rho_2\sigma_\gamma^2$ is the cross-diagonal interaction covariance, and $\rho_3\sigma_\epsilon^2$ is the cross-diagonal error covariance.

The complete derivation for the expected mean squares will not be presented here since it is rather lengthy; a copy of the derivation is available on request (Stoto, Kenny, & Warner, Note 1).

The number of untraditional variance components included in this expected mean square suggests that it will not be easy to find an appropriate error term that will make it

Table 5
Summary of Round Robin Design Specifications

possible to set up an F ratio to evaluate the significance of the row variance. Instead, we decided to solve directly for estimates of the variance components themselves; this requires seven equations in seven unknowns. Some additional sample mean squares are therefore needed, and the nature of these mean squares can be guessed from the set of unknowns appearing in EMS_{row}. The new mean squares are a mean square for row and column covariance (denoted $MS_{\text{Row}\times\text{Col}}$); a mean square for the covariance of cross-diagonal interaction effects (denoted $MS_{\text{Cell}\times\text{Cell}}$); and a mean square for the covariance of cross-diagonal errors (denoted $MS_{\text{Error}\times\text{Error}}$). Also, in setting up the sample mean squares, we have chosen to calculate a mean square for cells that is not the usual mean square for interaction; this was done because it is easier to evaluate the expected mean square for cells. The set of mean squares to be computed for the round robin layout are as follows:

$$MS_{\text{row}} = r\sum_i (M_{i..} - M...)^2,$$

$$MS_{\text{column}} = r\sum_j (M_{.j.} - M...)^2,$$

$$MS_{\text{cell}} = \frac{r}{n(n-1)-1}\sum_i\sum_{j\neq i}(M_{ij.} - M...)^2,$$

$$MS_{\text{Row}\times\text{Col}} = r\sum_i (M_{i..} - M...)(M_{.i.} - M...),$$

$$MS_{\text{Cell}\times\text{Cell}} = \frac{r}{n(n-1)-1}\sum_i\sum_{j\neq i}(M_{ij.} - M...) \times (M_{ji.} - M...),$$

$$MS_{\text{error}} = \frac{1}{n(n-1)(r-1)}\sum_i\sum_{j\neq i}\sum_k (X_{ijk} - M_{ij.})^2,$$

and

$$MS_{\text{Error}\times\text{Error}} = \frac{1}{n(n-1)(r-1)}\sum_i\sum_{j\neq i}\sum_k (X_{ijk} - M_{ij.}) \times (X_{jik} - M_{ji.}).$$

The coefficients for the variance components in the seven expected mean square equations corresponding to these sample mean squares are summarized in Table 6.

We now have the information necessary to solve for the estimates of the seven variance components. Let **M** be the (7×1) vector of

sample mean squares: (MS_{row}, MS_{col}, MS_{cell}, $MS_{Row\times Col}$, $MS_{Cell\times Cell}$, MS_{error}, $MS_{Error\times Error}$). Let $\mathbf{V}$ be the (7×1) vector of variance components to be estimated:

$$(\sigma_\alpha^2, \sigma_\beta^2, \sigma_\gamma^2, \rho_1\sigma_\alpha\sigma_\beta, \rho_2\sigma_\gamma^2, \sigma_\epsilon^2, \rho_3\sigma_\epsilon^2).$$

Let $\mathbf{C}$ be the (7×7) matrix of coefficients from the expected mean squares equations, as in Table 6.

By definition, $\mathbf{M} = \mathbf{CV}$. Therefore we can solve for estimates of the variance components by multiplying both sides by the inverse of the coefficient matrix, to get $\mathbf{V} = \mathbf{C}^{-1}\mathbf{M}$.

One can of course consider various special cases of the model as $\sigma_\alpha^2 = \sigma_\beta^2$ and $\rho_1 = 1$; $\rho_2 = 0$; $\rho_2 = 1$; $\rho_2 = -1$; $\rho_3 = 1$; or $\rho_3 = -1$. For any of the above assumptions one can simply drop the relevant mean square and change the coefficient matrix accordingly. In the case of $\sigma_\alpha^2 = \sigma_\beta^2$ and $\rho_1 = 1$, a sensible strategy would be to combine MS_{row} and MS_{column}, and drop $MS_{Row\times Column}$.

In order to ensure that all the parameters in the model are identified, it is necessary to have a minimum of four subjects. The model may be applied where $r = 1$ (each dyad is observed only once), but in this case it will not be possible to distinguish the interaction variance (σ_γ^2) from the error variance (σ_ϵ^2), or the cross-diagonal interaction covariance ($\rho_2\sigma_\gamma^2$) from the cross-diagonal error covariance ($\rho_3\sigma_\epsilon^2$).

Significance Testing

Once estimates of the variance components have been obtained, it is necessary to have some means of evaluating whether they differ significantly from zero.[2] A useful strategy is jackknifing (Mosteller & Tukey, 1977). The idea is to estimate the variance of a parameter by examining the empirical distribution of estimates of that parameter (such as σ_α^2), since there is no simple way to determine the variance of its theoretical distribution. For σ_α^2, for instance, this can be done as follows: First, create n different subsets of the data, each subset consisting of the full data matrix, omitting the data for one subject (i.e., one row and the corresponding column). For each of these leave-out-one subsets, we can estimate a value for σ_α^2. Now, these n different estimates of σ_α^2 are not independent, since the subsets overlap in membership; but Mosteller and Tukey have devised a way around this problem. A set of pseudoestimates is generated from the leave-out-one estimates, and the pseudoestimates can be treated as if they were independent. Let Y_{all} be the value of σ_α^2 for the whole group of n subjects; let $Y_{(j)}$ be the value of σ_α^2 for the subset of $n - 1$ subjects created by omitting person j. Then the pseudoestimates are given by $Y_{*j} = n(Y_{all}) - (n - 1)Y_{(j)}$, for $j = 1, 2, \ldots, n$. The Y_{*j} pseudoestimate is a "fake" estimate of σ_α^2, as if we had been able to estimate σ_α^2 based on only subject j; using this set of pseudoestimates, we can estimate the standard error

[2] To see why F ratios are difficult to set up, consider the expected mean squares associated with the ratio of mean square rows and mean square error. It is clear that this ratio would not be an unbiased estimate of the row effect variance.

Table 6
Expected Mean Square Coefficients

MS	df	σ_α^2	σ_β^2	σ_γ^2	$\rho_1\sigma_\alpha\sigma_\beta$	$\rho_2\sigma_\gamma^2$	σ_ϵ^2	$\rho_3\sigma_\epsilon^2$
Row	$n-1$	$r(n-1)$	$\frac{r}{n-1}$	r	$-2r$	$-\frac{r}{n-1}$	1	$-\frac{1}{n-1}$
Column	$n-1$	$\frac{r}{n-1}$	$r(n-1)$	r	$-2r$	$-\frac{r}{n-1}$	1	$-\frac{1}{n-1}$
Cell	$n(n-1)-1$	$\frac{r(n-1)^2}{n(n-1)-1}$	$\frac{r(n-1)^2}{n(n-1)-1}$	r	$\frac{-2r(n-1)}{n(n-1)-1}$	$\frac{-r}{n(n-1)-1}$	1	$-\frac{1}{n(n-1)-1}$
Row × Column	$n-1$	$-r$	$-r$	$-\frac{r}{n-1}$	$\frac{r[(n-1)^2+1]}{n-1}$	r	$-\frac{1}{n-1}$	1
Cell × Cell	$n(n-1)-1$	$-\frac{r(n-1)}{n(n-1)-1}$	$-\frac{r(n-1)}{n(n-1)-1}$	$\frac{-r}{n(n-1)-1}$	$\frac{2r(n-1)^2}{n(n-1)-1}$	r	$-\frac{1}{n(n-1)-1}$	1
Error	$n(n-1)(r-1)$	0	0	0	0	0	1	0
Error × Error	$n(n-1)(r-1)$	0	0	0	0	0	0	1

of σ_α^2 by the variance of the Y_{*j} values and use this to set up a t test (with $n - 1$ degrees of freedom) to evaluate whether $\sigma_\alpha^2 = 0$. Let y_* be the mean of the Y_{*j} pseudovalues, and let s^2 be the variance of the Y_{*j} pseudovalues. Then $(n^{\frac{1}{2}}y_*)/s$ is distributed as t with $n - 1$ degrees of freedom if $\sigma_\alpha^2 = 0$.

This jackknifing procedure can be used to test the significance of each of the variance and covariance components estimated for the model. For justification of the procedure and further examples of its applications, see Mosteller and Tukey, 1977 (chap. 8).

Interpretation of the Variance and Covariance Components

Since the components of this model differ from those of an ordinary analysis of variance, some comments on the meaning that the variance components have for various types of social interaction data may be helpful. Notice first that three variance components (actor, partner, and interaction) correspond to the components of an ordinary two-way analysis of variance and that three covariance components (row and column, cross-diagonal interaction, and cross-diagonal error) provide information somewhat similar to that of an intraclass correlation design.

Actor effect. This factor is related to individual differences among persons as sources of social behaviors; depending on the dependent variable, this factor can be renamed speaker, rater, perceiver, and so forth. Since each individual's behavior is observed over a number of different partners, the round robin analysis of variance provides a fairly strict test for stability; the actor effect cannot be large unless individuals are fairly consistent in their behavior, regardless of the person with whom they are paired.

Partner effect. This factor indicates whether there is a strong tendency for individuals to elicit particular types of behavior from other persons—for instance, high or low trait ratings, high or low level of attraction, high or low amounts of speech activity, and so forth.

Notice that it is possible to have a strong actor effect and a weak partner effect (this occurs in the vocal activity data presented in this paper as an illustration of the model) or a strong partner effect and a weak actor effect (as we have seen in preliminary work with person perception data, where the subjects are being trained to apply an objective rating system; there are small differences among ratings given by different raters and large differences in the ratings received by different individuals). Thus, although they are often highly correlated, it is important to stress again the logical distinction between these factors, and in some situations, particularly in person perception research, it is interesting to compare the magnitude of these two main effects.

Interaction effect. This component relates to the particular adjustment that each person makes to each particular partner. In vocal activity research, for instance, interaction effect indicates whether Person i paired with Person j consistently talks a little more (or a little less) than would be expected on the basis of i's talkativeness and j's tendency to elicit talk. This interaction effect also has meaning in person perception and attraction research—does Person i tend to like Person j more than would be expected on the basis of i's average liking and j's average tendency to inspire liking? The interaction effect picks up any tendency to make adjustments that are unique to each partner and hold up across repeated pairings with that partner. In a sense the interaction term measures what is unique to the interaction between partners.

Row and column covariance. If this covariance is very large relative to the row and column covariances, and if it is positive, it suggests that the row and column factors are nearly indistinguishable, in which case a single factor design (one that combines actor and partner into a single subject factor) may be more appropriate. In some situations, the row and column covariance may have a substantive interpretation; if the dependent variable is related to utility (for instance, the favorableness of a rating or the amount of some resource given by one person to another), then the relationship between the row factor (amount Person i gives out, on the average) and the column factor (amount Person i receives, on the average) may be viewed as a kind of "equity" factor. Another theoretical construct that comes close to describing this

factor in person perception is *projection*; a high row and column covariance could be taken to mean that the ratings a person gives to others are closely tied to his or her own traits (as perceived by others). For the vocal activity data, there is no simple interpretation of this covariance.

Cross-diagonal interaction covariance. This is one of the two dyadic reciprocity factors in the round robin design; it should be distinguished from the cross-diagonal error covariance, which picks up a different type of reciprocity. A large cross-diagonal interaction covariance means that for each of the possible (i, j) dyads, the systematic and enduring adjustment that i makes to j is correlated with the enduring adjustment that j makes to i. For interpersonal attraction data, it seems likely that this could be a strong relationship; that is, if i always tends to like j more than expected, it seems probable that in return j always tends to like i more than expected. The reciprocity picked up by this covariance is an enduring reciprocity, that is, a relationship between partner behaviors that holds up across different times or situations.

Cross-diagonal error covariance. This is a situation-specific reciprocity effect. If this covariance is large, then the behaviors of the partners are highly correlated in any particular situation, although they may not necessarily be related in the same way across different situations. For instance, in the vocal activity data, we will find a large cross-diagonal error covariance—since the proportion of time available for speaking in any particular conversation is approximately zero sum, the vocal activity of partners in specific conversations is highly negatively correlated. However, the reciprocity turns out not to be enduring—that is, although the sum of activity is approximately 1 in any particular conversation, the allocation of time between partners may be worked out differently in different conversations—in one, Person i may do more than his or her share of the talking; in the next, Person j may do more than his or her share. A fanciful example illustrating the independence of the situation-specific and the enduring reciprocity factors might be found in a soap opera, where the attractions and antipathies among the characters may be highly correlated and mutual in any one episode, but the pattern of attractions may shift from one week to the next—indicating strong situation-specific reciprocity and a lack of enduring reciprocity.

Summary

Clearly, the interpretation of the variance and covariance components in the round robin model depends upon the nature of the dependent variable and the type of substantive or theoretical questions that arise about the reciprocity of behaviors. The goal of this section is to show the flexibility of the new round robin model; there are some readily understandable parallels between well-known theoretical constructs and the factors in the round robin design. The following section will demonstrate the application of the round robin design to vocal activity data.

Empirical Illustration

Various aspects of speech activity in conversations and interviews have been singled out for study, for example, mean duration of vocalizations or pauses, probability of initiating or maintaining speech, and proportion of time spent speaking; these vocal activity parameters are interrelated, and certain aspects of vocal activity are highly consistent for individual speakers (Jaffe & Feldstein, 1970). Of these parameters, the simplest one to study is the proportion of time spent speaking, or speaker activity level. Past research on individual speaker consistency has generally involved at most two or three different partners; the round robin design provides a natural method of examining individual differences across many different partners in order to evaluate parametrically whether the reliable individual speaker differences claimed on the basis of this earlier research actually exist.

A round robin study of proportion of time spent speaking was conducted by Warner (Note 2). Eight participants (four male, four female) were enlisted for a study of conversation. Each of the 28 possible pairs conversed privately on 3 separate days for about 12 to 15 minutes each time. Each speaker's voice was recorded onto a separate channel of a

Note. X_{ijk} = the proportion of time spent speaking by Person i to Person j on Day k (in percent).

stereo tape. The participants wore headsets with noise-canceling microphones close to the mouth; this type of microphone arrangement, which was somewhat intrusive, was necessary because ordinary microphones allow too much spillage of voices between channels. The proportion of time spent speaking by each person was determined by using a computer voice-operated relay to detect the presence or absence of speech in each of the two channels of the tape-recorded conversations. The voice-operated relay was calibrated by means of an indicator light that showed when the system was detecting speech activity; thus a human listener could manipulate the threshold and other settings on the voice-operated relay until the pattern shown by the light matched the perceived on–off pattern of speech activity.

The on–off vocal activity judgment was made twice per second, and this information was used to determine the proportion of time spent speaking by each person over the time of the whole conversation.

Subjects were instructed that the study was about the process of becoming acquainted and were told that they could talk about whatever they liked. Pilot tests had indicated that this was probably much more natural than imposing some kind of task; most dyads had little difficulty in carrying on a conversation, and a number of conversations were quite animated and contained information of a rather personal nature. Subjects spent their free time between recording sessions in a lounge where they were free to talk.

An effort was made to promote a feeling of ease in the situation, at the cost of experimental control; for example, several persons in the study were previously acquainted, some of the conversations that took place for the tape recorder were continuations of conversations that had begun in the lounge, and many conversations continued after the tape recorder was turned off. Partly because of the marathon nature of the scheduling (the eight subjects spent three 8-hour days participating in the study), a certain amount of group cohesiveness developed. For all these reasons, it seems likely that the conversations reported in this study are more natural than those that have been elicited from persons who come into the laboratory "cold" for just one session or who converse via intercom without visual contact.

The proportion of time spent speaking was tabulated for all 84 conversations, and the results are displayed in the $8 \times 8 \times 3$ data matrix shown in Table 7.[3]

The O-Bird round robin analysis of variance program, which carries out all the calculations, parameter estimation, and significance testing as outlined in this paper, was run on these data.[4] The results are displayed in a modified source table, with t tests in place of the usual F ratios. Since the true variance components

[3] No transformation for proportional data (such as arcsine) was used, since none of the proportions were very near zero or one.

[4] The O-Bird program (in Fortran) is available from the second author.

(row, column, interaction) must be nonnegative, a one-tailed t was used for these three tests; the covariances (row and column, cross-diagonal interaction, and cross-diagonal error) can be either positive or negative, and so a two-tailed t is needed for these three tests.[5]

Discussion

There were two significant effects: (a) clear-cut individual speaker differences in activity level, as shown by the significant t value for row effect and (b) strong situational reciprocity between the speech of partners in particular conversations, as indicated by the significant t value for the cross-diagonal error covariance. No other effects were statistically significant (although the sizes and signs of all other effects were generally consistent with our expectations, which lends some additional plausibility to the model). Our results confirm earlier findings of individual differences; we also have information about the cross-diagonal error convariance, which can be interpreted as evidence of a situation-specific reciprocity of speech activity level. This was anticipated, since it is a common sense observation that the time allocation within any particular conversation is approximately zero sum, that is, the more time taken up by one speaker, the less time available to the other speaker. Thus, the proportions of time spent speaking by the two persons in a particular conversation (X_{ijk}, X_{jik}) are negatively correlated.

The partner effect was smaller than the speaker effect, which would suggest that the impact of partner activity level on an individual's speech production is not as great as the effect of his or her own "preferred" activity level. As anticipated, there was a negative covariance between the activity level of a person and that person's effect on other prople's activity level when he or she was their partner; however, this covariance was not significant, so it seems appropriate to conclude that the relationship between an individual's activity level and his or her tendency to elicit a high or low activity level from others is not so strong that these two factors should be considered equivalent.

There was a relatively modest and nonsignificant interaction effect. This can be rationalized as follows: although it is true that in any particular conversation between persons i and j they adjust their activity levels to each other to achieve a total proportion of time active of about 1.0, this adjustment can be made in a number of different ways, and the adjustment that they make in any one particular conversation is unique to that conversation and does not carry over to later conversations (at least, not in our study, which considers only three conversations per dyad). That is, in one conversation, i may talk a little more than would be expected (based on i's talkativeness and j's tendency to elicit talk); in another conversation, i may talk less than would be expected. The small interaction variance indicates that there is not a fixed adjustment for each dyad, so that when i talks to j, he or she always talks a little more (or less) than usual.

The cross-diagonal interaction covariance for these data is virtually zero. This is reasonable; if i's adjustment to j is not stable or fixed across different situations, it is not reasonable to expect a strong relationship between i's average adjustment to j, and j's average adjustment to i. Furthermore, even if these partner adjustments were consistent, as would be indicated if there were a large interaction effect, the adjustments in activity level might not necessarily be correlated for partners. Any combination is possible —depending upon the "preferred" activity levels of i and j, both partners could talk more, both partners could talk less, i could talk more and j could talk less, or j could talk more and i could talk less; any of these types of adjustment could conceivably be needed in order to work out the time allocation between partners. Since all these combinations can and do occur, on the average the covariance between i's adjustment to j and j's adjustment

[5] When testing whether a variance component is zero in the population, a one-tailed t is appropriate, since the true variance component in the population cannot be negative. Since the pseudovalues can be negative (and will be negative about half the time if the true variance component being estimated is zero), there is no reason why these pseudoestimates could not be t distributed. Of course, the covariance terms can be either positive or negative, so two-tailed ts should be used for the covariance terms.

Table 8
Source Table for Round Robin Analysis of Variance

Source	*MS*	Variance or covariance estimate	*t*(7)

*$p < .05$, one-tailed $t(7)$. **$p < .05$, two-tailed $t(7)$.

to i will be nearly zero. The small (virtually zero) covariance obtained for this cross-diagonal interaction covariance indicates a lack of enduring reciprocity in speech activity level—there is no adjustment that i always makes to j that is correlated with an adjustment that j always makes to i. It seems likely that certain other vocal activity parameters (such as mean switching pause duration) and other variables such as attraction, might show enduring reciprocity; but there seems to be no such effect for activity level of speakers.

The significant individual speaker differences, taken together with the nonsignificant interaction effect, suggest that the appropriate unit of analysis for proportion of time speaking is the individual person rather than the dyad. The strong situational reciprocity, together with the lack of enduring reciprocity, suggests that the reciprocity of speech activity levels depends heavily on situational factors—perhaps topic of conversation, time of day, moods of the participants, and so forth, rather than on some lasting "agreement" between partners as to their relative dominance or right to claim speaking time. At present the model is not set up to handle order effects, but it could be extended to account for predictable shifts in the time allocation between partners over time (if these occur).

Although the main focus of this discussion is interpretation of the significant effects, there are additional aspects of the results in Table 8 that bear further examination. It is possible to estimate correlations from the mean squares:

$$\hat{r}_1 = \frac{MS_{\text{Row}\times\text{Column}}}{(MS_{\text{row}} * MS_{\text{column}})^{\frac{1}{2}}} = -.7504,$$

and

$$\hat{r}_2 = \frac{MS_{\text{Cell}\times\text{Cell}}}{MS_{\text{cell}}} = -.5686.$$

The $\hat{r}_1$ is the correlation estimate for the relationship between the row and column factors that would be obtained directly from the raw data. It is a biased estimate of the true relationship between row and column factors; this can be seen by inspecting the set of variance components belonging to $EMS_{\text{Row}\times\text{Column}}$, EMS_{row}, and EMS_{column}. The ratio of these raw mean squares clearly does not provide an estimate of the true correlation ρ_1. The same problem applies to the estimate for r_2, which is also biased; however, no such problem arises in estimating ρ_3, which is just $(MS_{\text{Error}\times\text{Error}})/MS_{\text{error}}$.

An alternative means of estimating the correlations is to take ratios of the variance and covariance components derived from the round robin model, as follows:

$$\hat{\rho}_1 = \frac{\widehat{\rho_1\sigma_\alpha\sigma_\beta}}{(\hat{\sigma}_\alpha{}^2\hat{\sigma}_\beta{}^2)^{\frac{1}{2}}} = -.6582,$$

$$\hat{\rho}_2 = \frac{\widehat{\rho_2\sigma_\gamma{}^2}}{\hat{\sigma}_\gamma{}^2} = .1372.$$

Although the components of these new correlation estimates are unbiased, our initial experiences with them indicate that they may be unreliable. Also, just as estimates for the variance components of the round robin model can be less than zero due to sampling error, correlation estimates derived from the variance and covariance components may fall outside the range of plus or minus one, especially if the denominators are small. Thus some caution is in order when using or interpreting these correlation estimates. It should be kept in mind that correlations based on the raw data in a round robin–type layout do not estimate what they seem to be estimating. Such raw correlations are commonly reported in person perception literature; their interpretation is highly problematic.

Another useful strategy is comparing the magnitude of various effects. A simple instance where this may be substantively interesting is in person perception research, where it may be useful to know whether there is greater variability among the ratings that people give (rater or actor effect) or the ratings that people receive (partner effect); that is, is the trait in question "in the eye of the beholder" (influenced mainly by the person doing the rating)? Or is it a trait that different observers can agree upon, influenced mainly by characteristics of the person being rated? This comparison can be made by looking at the ratio (or the difference) between the row and column variance components, and the significance of the ratio or difference can be evaluated by jackknifing. This comparison of actor and partner effects was not significant for the vocal activity data, $t(7) = .635$. That is, even though the row variance was significantly greater than zero and the column variance was not significantly greater than zero, the row variance was not significantly greater than the column variance.

More elaborate comparisons among the variances can also be constructed. For example, for some applications it might be instructive to ask to what extent the variability of social behavior is accounted for by characteristics of the individuals (actor and partner effects) as opposed to characteristics of the dyad or the situation (interaction and error). To the extent that actor and partner factors predominate, social behavior can be viewed as additive; social interaction can be conceived of as a linear system, that is, a system with behavior that can be predicted from the behavior of its components. Such a test of additivity might take the following form:

$$A = \frac{\sigma_\alpha^2 + \sigma_\beta^2}{\sigma_\gamma^2 + \sigma_\epsilon^2}.$$

For our data, this ratio was significantly greater than zero, $t(7) = 2.44$, $p < .025$ one-tailed, based on the jackknifing of this ratio over different subsets of the data; that is to say, some nonnegligible amount of the variability in vocal activity level is accounted for by the components of the conversational system, the speakers themselves. Depending upon the nature of the research problem, other comparisons among variances can be set up.

Special Applications

As with any statistical model, the decision to use the round robin model depends on two considerations—first, whether the assumptions of the model are satisfied, and second, whether the model provides the desired information. It is possible to use the round robin model to analyze data on unconstrained social interactions in natural settings or to make group comparisons; however, it is important to realize that these data may violate certain assumptions of the round robin model.

Consider the type of study in which social interactions are observed in natural settings such as classrooms. One might count the number of aggressive or attention-getting acts by each child. Since such data violate the independence assumptions of ordinary chi-square and analysis of variance, one should not use these tests. Clearly each act within a given classroom is dependent to some extent on the other acts that occur within that classroom. This might suggest that the round robin model is suitable for these data; in addition to reciprocity effects, however, there are likely to be other forms of social influence such as modeling or shared attitudes toward particular class members. In postulating the round robin model, we assume that (except for the reciprocity covariances) the observations are independent, for example, h's behavior toward Person i is assumed to be uncorrelated with j's behavior toward i. Clearly if Person j imitates h's behavior or shares h's attitudes toward other individuals, the behaviors of h and j will be correlated. This means that the independence assumptions of the round robin model are violated. It may be possible to minimize these other forms of social influence by preventing the participants from observing the interactions of other dyads and preventing participants from discussing their perceptions and attitudes. In many natural social environments, however, this kind of control is not feasible, and the use of such stringent controls may sacrifice too much external validity.

We know of no statistical test of the covariance structure of the data to evaluate whether the independence assumptions of the round robin model are satisfied. Such a test could conceivably be developed along the lines of

work done by Huynh and Feldt (1970). In the absence of statistical criteria, the investigator must realize that modeling and shared expectations will bias the estimates of the round robin model parameters.

Another difficulty in the analysis of interaction data from unconstrained social situations is that participants self-select their partners and may not interact with everyone else in the group. This results in large numbers of missing observations or zero frequencies. At present the analysis we propose cannot handle missing data. The presence or absence of ties between persons reveals network structure, however, so block models or network analysis are viable alternatives (White & Breiger, 1975).

Another possible application involves group comparisons: either comparisons of two or more round robin layouts or comparisons of subsets of subjects within a round robin layout. For instance, the vocal activity study reported earlier included four male and four female participants. One might wish to examine differences in talkativeness between males and females or between same sex and cross-sex dyads. This might be done by taking the mean difference in the row effect estimates (α_i) for males versus females in such of the leave-out-one subsets of data and jackknifing to get a significance test. One might also wish to correlate the actor effect (α_i), talkativeness, with a personality scale such as dominance.

Another consideration in applications of the round robin model is sample size. The round robin analysis requires a minimum of four persons, and the jackknife procedure raises this to five. In fact, we believe that the analysis will provide unstable estimates for sample sizes less than eight. Recall that if there are only seven members of the group, there are only six degrees of freedom in the t test of the actor and partner main effects. To increase the efficiency in estimation, one can replicate the round robin design on different sets of persons. The parameter estimates could then be pooled across the different groups, resulting in more stable estimates.

Summary

The new round robin analysis of variance provides a tool for dealing with social interaction data that allows assessment of both individual differences and reciprocity in social behaviors. It readily lends itself to the substantive problems encountered in social psychological research on person perception, attraction, vocal activity and other mutually contingent behaviors. This means that instead of regarding the mutual contingency of social behaviors as a problematic deviation from the independence assumptions of statistical models traditionally used in the nonsocial sciences, it is possible to explicitly incorporate mutual contingency into the design and to treat it as an interesting effect in its own right. By tailoring statistical models to the questions that arise in social psychological research, we can leave behind some of the limitations that are inherent in the use of statistical models that were created to study nonsocial phenomena.

The round robin data layout is not new; this type of design has been employed in a number of classic social psychological studies (Campbell, Miller, Lubetsky, & O'Connell, 1964; Cronbach, 1955; Newcomb, 1961). It continues to be used in small group and person perception research (e.g., Bales, 1970). What is new is the statistical model specifically tailored to this design, which makes it possible to test the significance of individual differences, interaction effects, and various types of reciprocity. This new round robin model is ideally suited to the kind of research Tagiuri called for in his 1969 article on person perception in the *Handbook of Social Psychology*. He recommended more study of person perception in the context of ordinary transactions that occur in the natural environment, where the persons are interacting with each other and each person is simultaneously judge and object.

The round robin design deserves serious consideration as an alternate research strategy that provides information complementary to that from traditional experimental designs. We hope that the availability of techniques that facilitate analysis of data from naturally occurring social interactions will stimulate interest in the interactive, mutually contingent aspects of social behavior and the relationship between individual differences and social interaction.

The Independence of Evaluative and Item Information: Impression and Recall Order Effects in Behavior-Based Impression Formation

Elizabeth K. Dreben, Susan T. Fiske, and Reid Hastie
Harvard University

Impression and recall order effects were examined in the context of Anderson's information integration model of impression formation. Subjects read four items of information about each stimulus person and participated in one of five between-subjects conditions: (a) rated the stimulus person after the presentation of each item and, after the fourth rating, recalled the four items; (b) did the same, except that a trait-rating filler task was interpolated between each rating and the next presentation; (c) did the same, except that the filler task was math problems; (d) made only one rating, after the presentation of the fourth item, did no filler task, and did recall the four items; (e) did the same, without recall. In the first three conditions, each impression rating was affected most by the most recently presented item, whereas in the two final response conditions, there was a slight primacy effect. In contrast, task conditions had little effect on recall; serial position curves for all four recall conditions were U-shaped, exhibiting both primacy and recency, as commonly found in free recall research. Low and nonsignificant correlations between impression weights and recall, as well as the markedly different serial position curves, were discussed as evidence for distinct processes of recall and impression formation.

Recent theoretical analyses of human cognition have depended heavily on the concept of abstraction processes to explain performance in perception, comprehension, memory, and judgment tasks. For example, psychological models for visual perception (Minsky, 1975; Posner, 1969), sentence comprehension (Bransford & Franks, 1972; Schank & Abelson, 1977), verbal memory (Bartlett, 1932; Mandler & Johnson, 1977), visual memory (Mandler & Parker, 1976), and decision making (Kahneman & Tversky, 1972) have emphasized the abstraction of prototypes, data structures, semantic products, deep structures, schemata, and themes as the central component of cognitive information processing. An important empirical question concerns the relationship between mental representations of the concrete surface structure of the stimulus and the schematic structure that is abstracted from the original stimulus (e.g., Sachs, 1967).

The present research is concerned with the relationship between memory for concrete factual information about a person's behavior and an abstract evaluative impression based on that information. In particular, we will be concerned with the relationship between the importance or impact of an item of information on the abstract impression and the likelihood that that specific item is recalled in a subsequent memory test. Before we discuss our method for studying the impression–memory relationship, we will review relevant work on impression and memory processes considered in isolation from one another.

This article is based on the first author's undergraduate honors thesis. The authors acknowledge the helpful comments of Norman Anderson, David Green, and David Kenny.

Impression Formation Processes

In 1946 Asch introduced an impression formation task in which experimental subjects are shown a sequence of trait adjectives attributed to a single fictional person and are asked to judge the person's personality. This task has dominated research on social judgment during the past 30 years. Anderson's information integration theory (e.g., 1974) averaging model provides the most popular and most thorough account for the impression abstraction process in the Asch task. Anderson's model prescribes that information from stimulus elements or cues will be integrated according to an averaging rule to produce a response. Quantitatively:

$$R = w_1 s_1 + w_2 s_2 + \cdots = \sum_{i=1}^{n} w_i s_i$$

where w_i = weight and s_i = scale value.[1] The subscripts refer to the serial positions of the piece of information in the sequence (i.e., $w_1 s_1$ denotes the weight and scale value of the first trait in an Asch task). The restriction that the weights must sum to one makes the model an averaging model.

One major finding obtained in the Asch paradigm concerns *order* effects. In general, early information seems to have a greater effect on the response than does subsequent information, creating a primacy effect. However, given certain task conditions, such as continuous responding, final recall, and others, recency effects occur.

According to Anderson's averaging model, primacy occurs when the relative weights of the first items are larger than the relative weights of the last items. Recency occurs in the reverse situation, when the last items are weighted more heavily than the first items. The averaging model is used to estimate the effects of each serial position on the final rating. (These serial position effects are proportional to the weights in the averaging model.)

Anderson suggests both an inconsistency discounting explanation and an attention decrement explanation to account for the changing weights that cause the primacy effect. According to the discounting explanation, later adjectives that are inconsistent with earlier adjectives are discounted and weighted less. The attention decrement hypothesis posits that the earlier information counts more because the subjects attend less to each subsequent piece of information.

Several experiments have been designed to test between these explanations by varying certain requirements of the standard procedure. Stewart (1965) found the primacy effect when the subjects made only one rating after all the adjectives were presented, but he found a recency effect when subjects made a rating after each adjective. Anderson (1968) obtained recency when subjects pronounced aloud each adjective after it was presented. This recency occurred when final, continuous, and intermittent (rating once in the middle as well as at the end) response conditions were used. Hendrick and Constantini (1970) varied the degree of inconsistency between the traits and found that intertrait inconsistency did not change the primacy effect. They observed a recency effect when pronunciation of each adjective was required, and primacy without the pronunciation requirement.

The results we have just reviewed are all supportive of the attentional account for serial position effects in impression formation. Only one result in the impression formation literature appears to contradict such an account. Hendrick, Constantini, McGarry, and McBride (1973) found that variations in the time interval between trait presentations (1 to 5.8 sec) did not affect primacy. However, even this result is not unequivocally contrary to attentional accounts. Thus, we have emphasized attentional mechanisms in our theoretical analysis of the present experimental task.

To look at order effects in greater detail, Anderson and Farkas (1973) used an experimental design that permitted estimation of serial position weights. They used a continuous response task and found recency in the

[1] For the purposes of this discussion the scale value and weight of the initial impression (designated $w_0 s_0$) are ignored.

last serial position (for each rating), with the early portions of the curve being flat. Their explanation, seen as a specification of the attention decrement hypothesis, postulates a *surface* component that refers to the short-term recency effect, reflecting the immediate reaction to the stimulus just presented and a *basal* component that represents the stable component of the impression reflected in the flat portion of the curves. Fluctuations in the content of the surface component correspond to variations in attention.

One experiment in this tradition was concerned with the impression–memory relationship that is central in the present investigation. In 1963 Anderson and Hubert conducted an impression formation experiment that replicated the standard primacy effect obtained in earlier research. When subjects were told they would be asked to recall the adjectives, however, they found reduced primacy and, in one condition, a slight recency effect. Anderson and Hubert also found a strong recency effect for recall in all conditions, even when there was a primacy effect on the impression. They cited the impression results as evidence for their attention decrement hypothesis. The reduced primacy was interpreted as evidence that subjects anticipating recall equalized attention to all items as they were presented. More importantly, Anderson and Hubert concluded that the difference between impression and recall serial position effects implied "that the formation of the impression involves a memory process which is distinct from, and not dependent on, the immediate verbal memory for the adjectives just heard" (Anderson & Hubert, 1963, p. 386).

Free-Recall Memory Processes

The free-recall paradigm in memory research is analogous to the Asch impression formation task. In free recall the serial position effect is usually in the form of a bow-shaped curve (Klatzky, 1975). There is a primacy effect, followed by an asymptote in the middle section and then a recency effect. Variables such as rate of presentation, word frequency of occurrence in English, and list length variations affect primacy and asymptote portions of the curve (Glanzer, 1973). Variations in delay between study and recall affect the recency portion. These results support the two-component memory hypothesis, that is, that there is a limited short-term store and a very large long-term store.

It is important to note that the simple two-store model is not universally popular. For example, one result, apparently discrepant from the two-component theory, is that of Bjork and Whitten (1974). They used distractor-delay tasks to interfere with the short-term component and thereby eliminate recency effects. These variations did not affect recency, however, and so Bjork and Whitten concluded that long-term storage must underlie the recency effect.

Overview

The present experiment used the Anderson and Farkas (1973) design with continuous responding and includes the Anderson and Hubert (1963) free recall measure. In addition, the Bjork and Whitten (1974) interpolated distractor task, or delay between the serial positions, was also employed. The logic of our examination of the impression–recall relationship is an extension of the Anderson and Hubert (1963) reasoning. The focus is on the correlation between the forms of impression weight and recall probability serial position curves. However, we carry the analysis forward in two respects: first, by examining complete position-by-position serial curves, and second, by varying interpolated response tasks that previous research has shown will affect impression and memory processes. Two interpolated response tasks were chosen, math problems and trait ratings, because we predicted that they would have differential effects. Since traits are relatively similar to behavior sentences, we hypothesized that the trait task would interfere more on both the impression and recall tasks than would the math task.

Two recent papers (Riskey, 1979; Rywick & Schaye, 1974) report related extensions of the Anderson and Hubert approach. For the present, we will only note that these investigations reached contradictory conclusions on

the issue of the impression–memory relationship. Riskey concurred with Anderson and Hubert that abstract impression and item specific representations are independent while Rywick and Schaye concluded that the impression was dependent on specific item information in long-term memory. We will discuss these results more thoroughly after we have described our own empirical investigation.

Method

The subjects completed ratings of eight sequences, each of which was composed of four sentence pairs describing a person. We used sentences describing behaviors, instead of traits or paragraphs, because people often use sentences involving behaviors in person descriptions (e.g., Fiske & Cox, 1979). There were five experimental conditions: three continuous response groups who made a cumulative likability rating after each sentence pair and were asked to recall as much as possible after the fourth or final rating for each stimulus person, and two final response groups who made only one rating after the fourth sentence pair for each stimulus person.

Subjects

Eighty Harvard-Radcliffe undergraduates recruited as paid subjects were tested in groups of 1 to 5 people, with each subject in a separate cubicle. Subjects tested at the same time were always in the same experimental condition. The continuous response groups were tested as one phase of the experiment, and the final response groups were tested 5 months later. The five experimental conditions can be compared, as experimental procedures were uniform for all groups.

Procedure

There were five cover sheets, three for continuous and two for final responding. In the first continuous responding group (no-task condition), the subjects were instructed to read two sentences about a person and then to make a rating below the sentences on an unmarked 200-mm scale with endpoints labeled *most likable* and *least likable*. They were to turn the page when told and then were to read another two sentences. They then made a rating based on all the previous information. They were told that after four ratings they would be asked to recall as much as possible about the stimulus person.

The two other continuous responding groups included the same tasks described above, but added a task in between each page for sentence pairs. The alternating task was either a page of multiplication problems (math condition) or a page of trait ratings (trait condition). Instructions were to read and rate a person and, upon signal, to turn the page and work on a separate task. The alternating tasks would be repeated four times (after each sentence pair) and would be followed by the recall task.

In the fourth condition (final-only condition), subjects were instructed to read two sentences about a person, and on signal they were to turn the page and read another two sentences. After four sentence pairs a final likability rating was made. In the fifth condition (final with recall condition), instructions were the same as those in the fourth condition, except that the likability rating was followed by the recall task.

During the experiment, subjects were given 10 sec to read and rate each sentence pair, 30 sec for the second task (in the alternating conditions), and 90 sec for the free-recall measure.

Stimuli

The stimuli were pairs of sentences, with each pair composed of either a positive sentence and a neutral sentence or a negative sentence and a neutral sentence. An example of a positive–neutral pair is "Alan bought groceries for an elderly lady next door who was ill" and "Alan pressed the button and waited for the elevator to come." For generalizability of stimuli, and so that each sentence appeared only once for each subject, there were 64 sentences (8 stimulus people each composed of 8 sentences): 16 positive, 16 negative, and 32 neutral. To insure that the sentences within each category (i.e., positive, negative, or neutral) would be considered roughly equivalent in terms of likability, the sentences were pilot tested before the experiment was conducted. The mean and spread of ratings for a larger group of sentences was examined, and 64 sentences were chosen (with the lowest positive mean at 139.40, the highest negative mean at 49.75, and the neutral means ranging between 93.05 and 105.15 on a 200 mm scale).

Design

The design is a $5 \times (4 \times 2)$ factorial design, with one between-subjects variable and two within-subjects variables. The five-level variable is the subject's task during the experiment session that was introduced above. The four-level repeated measure is serial position (1 through 4) and the two-level repeated measure is (high or low) valence.

In order to reduce the number of observations per subject, the research used a half-replication of the 2^4 design [2] (e.g., Cochran & Cox, 1957) with 8 sequences

[2] The half-replicationof the 2^4 design was analyzed as a 4×2 within-subjects design. The four-level factor corresponds to input serial position and the two-level factor corresponds to item valence at each position (evaluating positive or negative).

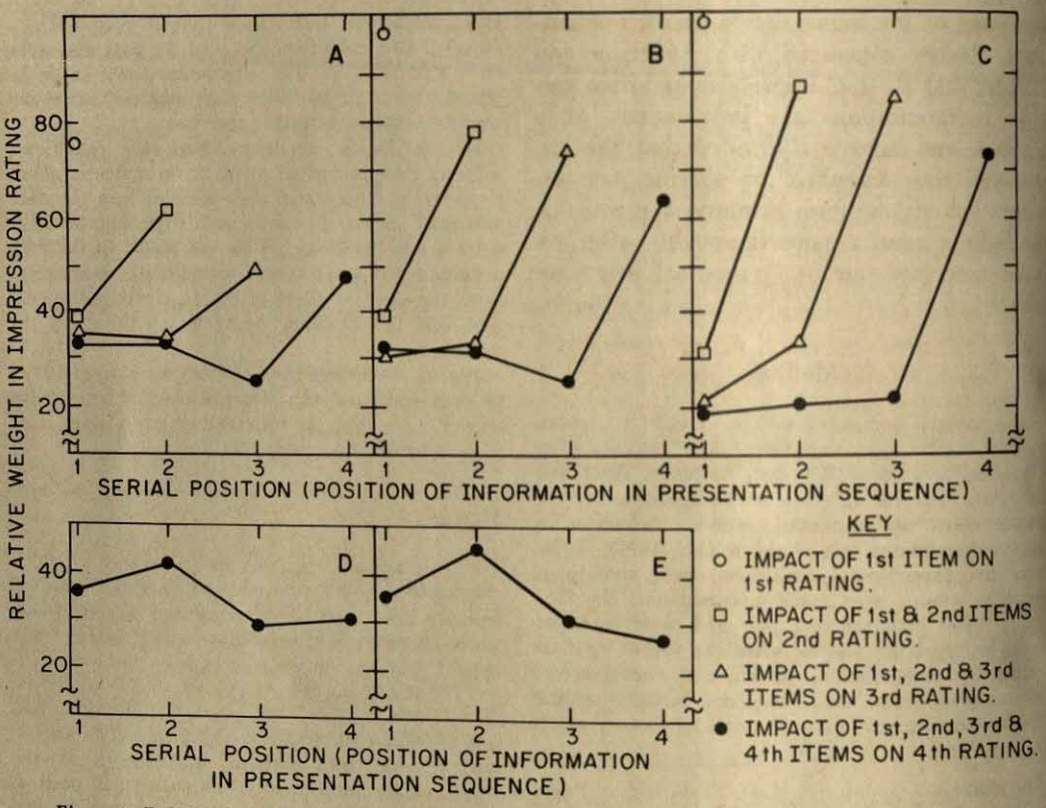

Figure 1. Relative impact of information presented at first through fourth positions on impression ratings made after each position. (Note that each subject in Panels A–C made four ratings, and the impact of the most recently presented item was always the greatest. Conditions in which subjects made only one rating, Panels D and E, show no recency and some primacy. The five panels represent the between-subjects task conditions: [a] four impression ratings, one after information presented at each serial position, and a recall task after fourth rating [no-task condition]; [b] four ratings, final recall, and irrelevant trait-rating filler after each rating [trait condition]; [c] four interpolated ratings, final recall, and irrelevant math filler after each rating [math condition]; [d] final rating, final recall, and no filler [final with recall]; [e] final rating only, no recall, and no filler [final only condition].)

(each containing 4 sentence pairs) instead of the full 16. Each half-replication was counterbalanced in an 8×8 Greco-Latin square so that both stimulus people and sentence pairs occur equally often in all positions. This ensured that order of presentation was not confounded with the order effects under study. A complete replication of this design requires 8 subjects in each condition. Two replications of the design were run with 16 subjects for each between-subjects condition, making 80 subjects in all.

Results

Impression Order Effects

The main analysis was done on the final impression rating, Rating 4. There was one between-subjects variable, task condition (math/trait/no task/final with recall/final only) and two within-subjects variables, position (four levels) and valence (high/low, or H/L).

Overall, the continuous responding conditions showed recency, and the final responding conditions did not. The serial position curves (serial position weights) calculated for each of the four ratings for no task, trait, and the math conditions are displayed in Figure 1 and clearly show a recency effect. In contrast, subjects in the final response conditions showed a primacy effect. The differential effects of serial position are illustrated by the main effect for position, $F(3, 225) = 10.88$, $p < .001$. The serial position weights in Table

1 show that Position 4 has the greatest impact on the final rating for the continuous response conditions but not for the final response conditions.

The most sensitive tests of the effects of the experimental tasks are the planned contrasts differentiating among the shapes of the five task condition serial position curves. These contrasts partition the variance from the significant Task × Serial Position interaction effect, $F(12, 225) = 4.36$, $p < .001$. The task main effect was nonsignificant ($p > .5$). The striking effect in this analysis was the comparison between the final and continuous responding conditions on the linear effect, $F(1, 225) = 21.29$, $p < .001$.

As in previous research using similar tasks and the serial position counterbalancing plan (Anderson & Farkas, 1973), several higher order interactions, concentrated in the Serial Position × Task × Replication effects, were significant.

Recall Order Effects

The dependent measure for the recall task was the number of valenced (H or L) sentences recalled from each of the four serial positions. The amount of recall at each position was analyzed, using analysis of variance for the four-level within-subjects variable of serial position, the two-level within-subjects variable valence (H or L), and the between-subjects variable of task (trait/math/no task/final with recall). The recall task showed the standard U-shaped curve (both primacy and recency) for all the conditions, although there were differences in the sharpness of the curves depending on the condition. Figure 2 shows the serial position effects in which the no-task condition exhibits the largest primacy and recency effects. The math and final with recall conditions show intermediate curvature across serial positions, whereas the trait condition exhibits the flattest curve. These results are reflected by the significant Task × Serial Position interaction, $F(9, 180) = 2.10$, $p < .05$, which shows the differential position effects as a consequence of experimental condition.

There was a main effect for serial position, $F(3, 180) = 19.23$, $p < .001$, which indicates that the location of a valenced sentence influenced how likely the sentence was to be recalled. The task main effect was nonsignificant. There was also a main effect for valence (H or L), $F(1, 160) = 30.84$, $p < .001$, such that negative information was recalled more frequently than was positive information across all serial positions.

The number of errors in recall (either intrusions of previous stimuli presented or recall made faulty by the inclusion of stimuli) were analyzed, and there were no patterns for either serial position or task effects. (The error rates were very low; for intrusions, $M = .15$, and for faulty recall, $M = .07$.)

A separate analysis of the recall of neutral sentences revealed only a significant main effect for serial position, $F(3, 180) = 7.33$,

Table 1
Relative Influence of Each Serial Position on Final Impression Rating

Serial position	Task condition: Four ratings, math filler, with recall	Four ratings, trait filler, with recall	Four ratings, no filler, with recall	Final-only, no filler with recall	Final-only, no filler, without recall	Row *M*
First	17.64	32.31	33.34	34.99	35.02	30.66
Second	22.89	36.06	35.56	41.78	45.92	36.44
Third	25.11	24.34	25.78	29.70	30.83	27.15
Fourth	71.30	65.50	46.31	30.82	27.23	48.23
Column *M*	34.23	39.56	35.25	34.32	34.75	35.62

Note. Table entries are proportional to information integration weights (for derivation, see Anderson & Farkas, 1973).

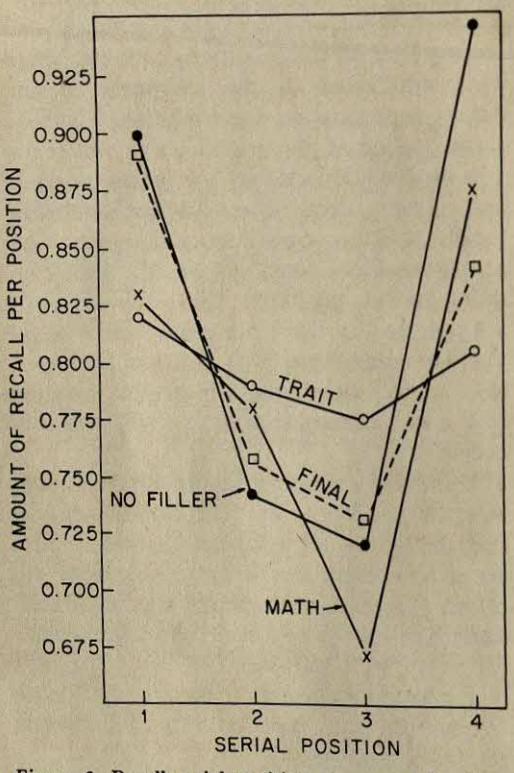

Figure 2. Recall serial position curves for the four between-subjects conditions in which recall was tested: no task (labeled *no filler*), math interpolated response task, trait rating interpolated response task, and final rating with recall task.

$p < .001$. Neutral sentence recall exhibited the typical U-shaped serial position curves but no other systematic patterns.

Relationships Between Impression and Recall

Overall, recall curves differ markedly from the impression serial position curves. In particular, there is a clear primacy effect for recall in all task conditions—although there is no such effect for impressions in continuous responding task conditions. It seems that earlier information is not forgotten, but it is given less weight in impressions.

At a finer level of analysis, correlations were calculated to measure the degree to which total valenced recall at each position corresponded to differential serial position weights. For the correlations, the impression difference scores (positive minus negative information *for each position*) were calculated on the final (fourth) likability rating.[3] Examination of the mean correlations pooled across the four serial positions for each of the four relevant between-subjects conditions (trait/math/no task/and final with recall) shows that none of these four pooled mean correlations is significantly different from zero. But the no-task and math conditions ($r = .28$ and $r = .38$ respectively) show a higher correlation between recall and differential impression rating than do the trait and final with recall conditions ($r = -.15$ and $r = .14$). Thus there is a low but nonsignificant degree of correlation between recall and differential likability ratings.

Discussion

The focus of the present experiment is on the relationship between an abstract personality impression and the specific items of information on which that impression is based. Anderson and Hubert (1963) and Riskey (1979) have conducted research that uses a method similar to the present experimental paradigm and have concluded that the impression, once formed, is independent from the representation of specific item information in memory. Our conclusion is in agreement with these investigators but is based on research with rich behavioral stimulus materials, involves an extensive variation in subjects' processing tasks, and includes a more detailed analysis of impression and recall results than

---

[3] For the Rating 4 analysis only, because half-replications were used in this design, the higher order interaction effects are confounded with replication. The difference score at Position 4 is equal to the four-way interaction of Replication × Difference Score at Position 1 × Difference Score at Position 2 × Difference Score at Position 3. The pattern of the first three positions in any sequence is identical for the two replications (i.e., HHH). It is the fourth sentence pair (H or L) that differs for the two replications.

The valence of the information at Position 4 is determined by the levels of Positions 1–3 and replication (1 or 2). Thus, the alias for Position 4 is the interaction of Position 1 × Position 2 × Position 3 × Replication (Cochran & Cox, 1957, p. 276). Since the other three ratings were not affected by the information at Position 4, that factor could be dropped from the design.

earlier experimental work. In this discussion we will briefly summarize our analyses of impression and recall results and then end with a theoretical note on the significance of these results in the context of the conclusions of Anderson and Hubert and of Riskey.

Impression Order Effects

First, the present results using sentences as stimuli reproduce the impression order effects obtained in previous research using traits, paragraphs, or photographs (Anderson & Farkas, 1973; Anderson & Lampel, 1965; Asch, 1946). This suggests that information embodied in the sentence descriptions of behaviors is used in the same way that information contained in the other stimulus materials is used. Thus, order effects do not seem sensitive to the stimuli used (traits, sentences, or paragraphs). This insensitivity is in marked contrast to the dependency of order effects on the method of presentation of the stimuli. As mentioned earlier, continuous responding (these data; Anderson & Farkas, 1973; Stewart, 1965), pronouncing aloud (Anderson, 1968), and warned recall (Anderson & Hubert, 1963) all serve to change the primacy effect into a recency effect. Thus, although the order effects are fragile in the sense that they can be changed when task requirements change, these same order effects are quite stable across variations in the stimuli employed.

Second, the final versus continuous responding variation in impression rating task requirements clearly affected the shape of the serial position curve, as shown by recency effects with continuous responding and no recency with final responding (Panels A, B, and C vs. Panels D and E in Figure 1). The distractor conditions (math and trait tasks) showed more recency than did the no-task condition (Panels B and C vs. Panel A in Figure 1). The impression-irrelevant math problems and trait ratings may interfere with the process of impression formation, with the interruptions leading subjects to weight immediate information the most in their ratings.

Third, the current no-task condition (Panel A in Figure 1) replicated the Anderson and Farkas (1973) recency effect, and our addition of a warned recall task did not change the impression serial position curves. This differs from the Anderson and Hubert (1963) finding that warned recall decreased the primacy effect and sometimes produced recency.

Finally, the results for all conditions suggest that negative information has more weight than positive, which accords with the negativity effects in the impression formation literature (Kanouse & Hanson, 1972).

Recall Order Effects

The recall curves for the no-task, math, and final with recall conditions (see Figure 2) are the usual U-shaped curves obtained in the free-recall task. The trait condition curve is flattest but also shows slight primacy and recency effects. Although the time elapsed between the start of the no-task and final with recall conditions and the recall task was 2 minutes shorter than in the distractor conditions, the math recall curve is quite similar to the curves from the nondistraction conditions. The reduced recency in the math and trait conditions could be due to either the four distractor tasks themselves or to the final distractor task, which delayed the recall task.

The trait recall curve, considered in isolation, is interesting because the Bjork & Whitten (1974) finding of recency in the presence of a distractor task was not replicated. In one experiment, word pairs were presented, with simple multiplication problems between each pair and further multiplication before the recall task. They obtained a U-shaped curve and suggested that this was evidence for long-term store effects on recency. In another experiment, they found similar recency effects, whether or not there was a 30-sec final delay before recall, as long as the interpolated task between each word pair was presented. This is further evidence, according to Bjork & Whitten, that recency results from a long-term memory process.

Bjork and Whitten suggested that the discriminability between items to be remembered caused the recency effect and is produced by using distractor tasks. These interruptions temporally separate the stimuli to make each

piece of information distinct. The current results cast doubt on this explanation. Although the math condition, which is similar to their interpolated task, replicated Bjork and Whitten's recency effect, the trait condition did not. It seems likely that the nature of the distractor task is important and that these tasks do not simply temporally distinguish between the stimuli. The distractor task may make the items more distinct by means of a figure–ground relationship. Since the math is clearly different from the verbal stimuli, it may separate each item of information more than do traits, which are more similar to sentences.

Relationships Between Impression and Recall

Under continuous rating conditions, subjects clearly weight the earliest information the least in their final impression rating, but this is not because they no longer remember it. All of the relevant recall serial position curves show clear primacy and recency effects. A more complete summary of the relationship between mean recall and mean impression weight would be obtained by plotting the mean recall at each position (points plotted in Figure 2) against the impression serial position weights on Rating 4 (solid points in Figure 1). Such a summary reveals that there is no simple relationship between recall and impressions, at least as indicated by their respective mean serial position curves. The nonsignificant correlations between recall and differential impression ratings based on the data from each individual character were reported above as further evidence that no simple relationship between memory and the impression exists.

The final responding conditions provide a replication of the Anderson and Hubert (1963) and the Riskey (1979) findings. Impression serial position curves show slight primacy and no recency, whereas recall serial position curves show dramatic recency and some primacy. Our interpretation of these results is in complete agreement with the Anderson and Hubert and Riskey accounts. Attention decreases across the sequence of stimulus items, producing the primacy effect in the impression serial position curve. Memory for individual stimulus items is not relevant to the impression, once their evaluative content has been integrated into the current impression. Thus, the U-shaped memory serial position curve is unrelated to the monotonically decreasing impression serial position curve.

A somewhat different picture emerges from an examination of results from continuous responding conditions. Here a large recency effect is consistently obtained for the *most recent item* on each of the four likability ratings. Anderson and Farkas (1973) have proposed a two-component model for a similar task, distinguishing between *surface* and *basal* components of an impression. Our interpretation is that each impression rating is dependent on information immediately available in short-term memory (surface component) as well as on the enduring impression that has accumulated across all previous stimulus events (basal impression). Thus, under continuous responding conditions the impression rating *is* dependent on immediately available item information as well as on the more abstract, item-independent, cumulative impression. The increase in recency effect magnitude with increasingly demanding tasks interpolated between ratings (no task *to* trait task *to* math task) adds support to this interpretation. (Note that this ordering of tasks by difficulty or cognitive demand is a post hoc interpretation.)

The present results from both final responding and continuous responding task conditions are quite consistent with an account based on attentional mechanisms (Anderson & Hubert, 1963; Riskey, 1979) and on a surface–basal component distinction (Anderson & Farkas, 1973). The emphasis on attentional mechanisms is strengthened even further by a detailed comparison of response requirements in continuous and final responding rating tasks. Under continuous responding conditions, the impression rating scale was printed on each page *containing* behavior descriptions, located below those descriptions. These are the conditions under which large recency effects were obtained. Thus, the information that has a large impact on the rating is not only recently avail-

able to comprehension and short-term memory mechanisms, it is directly available in the visual (attentional) field. On the other hand, under final responding conditions, the final (single) rating scale was printed on the page *following* the last page of behavior description sentences. Thus, under final responding conditions where no recency and slight primacy effects were obtained, immediate attention was not dominated by the final most recent information.

We would like to close this report by noting that our conclusion is an argument for the relative independence of a general abstract impression and the specific information on which the abstraction was based. Furthermore, we have cited a simple attentional mechanism as an explanatory principle to account for the differential impact of recent events on the evaluative impression under continuous and final responding conditions. This explanation presents a picture of the subject as a person whose behavior is stimulus driven and whose thoughts are dominated by the immediate environment (Kahneman & Tversky, 1972; Taylor & Fiske, 1978). Although we believe our subjects' judgments were dominated by the given stimulus information, we also attribute considerable cognitive complexity to comprehension, valuation, and integration operations that are assumed to underlie the impression formation process.

Instructions for Submission of Manuscripts

Papers submitted to the *Journal of Personality and Social Psychology* after April 1, 1979 will be considered under new policies approved by the Publications and Communications Board. Effective with the 1980 volume of the journal, the following policies will apply:

The *Journal of Personality and Social Psychology* publishes original papers in all areas of personality and social psychology. It emphasizes empirical reports but may include specialized theoretical, methodological, and review papers. Beginning in April 1980, the journal will be divided into 3 independently edited sections: ATTITUDES AND SOCIAL COGNITION, INTERPERSONAL RELATIONS AND GROUP PROCESSES, and PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES. Authors should submit manuscripts to the appropriate section editor according to the section definitions and manuscript preparation instructions provided on page 468 of the March 1979 issue of the journal.

Section editors' addresses are as follows: ATTITUDES AND SOCIAL COGNITION, Melvin Manis, Editor, Research Center for Group Dynamics, Institute for Social Research, University of Michigan, Ann Arbor, Michigan 48106; INTERPERSONAL RELATIONS AND GROUP PROCESSES, Ivan D. Steiner, Editor, Department of Psychology, University of Massachusetts, Amherst, Massachusetts 01003; PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES, Robert Hogan, Editor, Johns Hopkins University, Department of Psychology, 33rd and Charles Streets, Baltimore, Maryland 21218.

Self-Focus, Felt Responsibility, and Helping Behavior

Shelley Duval, Virginia Hensley Duval, and Robert Neely
University of Southern California

Two experiments were designed to determine if juxtaposing self-focus and salient distressed others would (a) increase self-attribution of responsibility for those needy others and (b) increase willingness to help those others. In Experiment 1, these hypotheses were tested by exposing subjects to their images on a TV screen 4 minutes before, immediately before, immediately after, or 4 minutes after seeing a videotape on victims of the venereal disease epidemic. As predicted, results indicated that subjects who saw their images immediately before or after seeing the videotape on victims of venereal disease felt more responsibility for and were more willing to help that group than did subjects in other conditions. In Experiment 2, subjects filled out a biographical questionnaire either 4 minutes before or immediately before seeing a videotape on poverty-stricken Latin Americans. Results from this experiment also confirmed predictions. Subjects who filled out a biographical questionnaire immediately before seeing a videotape on poverty in Latin America felt more responsibility for and were more willing to help the distressed group than did subjects who completed the questionnaire 4 minutes prior to exposure to the tape on Latin American poverty. Additional evidence indicated that this effect is probably not mediated by the sole operation of the self-evaluative mechanism posited by Duval and Wicklund or by any change in attitudes or norms regarding the distress of and/or necessity of helping distressed others. Implications of the self-focus/felt responsibility/helping behavior relationship for the general study of helping behavior are discussed.

Research clearly demonstrates that helping behavior is related to feelings of responsibility for the welfare of others in distress (Geer & Jarmecky, 1973; Schwartz, 1973; Schwartz & Clausen, 1970; Tilker, 1970). This relationship between feelings of responsibility for the welfare of others and helping behavior can be stated within the theoretical framework of attribution theory. Factors that increase self-attribution of responsibility for a distressed person will increase helping behavior. Factors that decrease self-attribution of responsibility for a distressed person will decrease helping behavior.

In retrospect, research based on an attributional approach to helping behavior (Ickes, Kidd, & Berkowitz, 1976; Piliavin, Rodin, & Piliavin, 1969; Schopler & Matthews, 1965) appears (with one exception, Wegner & Schaefer, 1978) to have been guided by one general question: What factors affect a person's attribution of responsibility, given that the attributional processes are governed by rational rules or schema such as discounting? Recent developments in attribution theory (Duval & Duval, in press; Duval & Hensley, 1976; Jones, 1976) indicate that attribution does not always conform to the logical patterns dictated by reason or common sense. This suggests that an attributional approach to the study of helping behavior might also attempt to determine what conditions affect a person's attribution of responsibility, given that the attribution processes are not strictly governed by rational rules. The present research is addressed to this question. Specifically, two studies were designed to determine whether conditions that affect the focus of attention also affect self-attribution of re-

sponsibility for the welfare of distressed persons and thus helping behavior.

Heider (1958) suggests that attribution of responsibility reflects the processes of unit formation. To the extent that conditions produce a unit relationship between some agent and some effect, that is, some event or situation, responsibility for the effect will be attributed to the agent. Duval and Duval (in press) and Duval and Hensley (1976) propose that the focus of attention is one variable that affects this process. To the extent that attention focuses on an agent, B, rather than on A, C, or others, the tendency to link B and an effect, X, in a unit relationship and thus to attribute responsibility for X to B should increase. Data from several studies support this hypothesis (Arkin & Duval, 1975; Duval & Wicklund, 1973; Pryor & Kriss, 1977; Storms, 1973; Taylor & Fiske, 1975).

Applied to a situation in which the distress of other persons is or becomes salient, the focus of attention–attribution hypothesis suggests that increasing self-focus will increase self-attribution of responsibility for the welfare of these distressed persons. Given the relationship between felt responsibility and helping behavior, increasing attribution of responsibility for distressed persons to self should in turn increase willingness to help those distressed persons. In order to test these two hypotheses, subjects were exposed to a stimulus designed to increase self-focus for 1 minute either 4 minutes before, immediately before, immediately after, or 4 minutes after they saw a documentary videotape designed to increase awareness of the plight of victims of the venereal disease (VD) epidemic. Attribution of responsibility for the welfare of VD victims and willingness to help VD victims were then measured. It was predicted that subjects in the immediately before and after conditions would feel more responsible for and would be more willing to help victims of VD than would subjects in the 4-minute before or after conditions.

Before turning to the experimental procedure, we might briefly discuss the basis for the predictions regarding the temporal interval between focusing on self, presentation of the distressed group, and attribution of responsibility to self, as well as the rationale for choosing victims of VD as the potential recipients of help.

The prediction regarding time interval, focus of attention and self-attribution is derived from the unit formation principle of temporal proximity. This principle states that decreasing the time interval that separates the presence or occurrence of an agent and an event increases the tendency to attribute responsibility to the agent and vice versa (Heider, 1958). Data from Michotte (1963) clearly support this prediction. We propose that the principle of temporal proximity applies not only to the time interval that actually separates the presence or occurrence of an agent and an event but also to the time interval that separates periods of increased awareness of the agent and the event. From this perspective, decreasing the time interval that separates the periods of increased focal awareness of self and increased awareness of a situation, such as the distress of VD victims, should increase the tendency to link self and the situation in a unit formation. According to Heider (1958), this increased tendency should lead to greater attribution of responsibility for the welfare of VD victims to self. Thus, subjects who experience increased self-focus immediately before seeing the videotape about VD victims should attribute greater responsibility for the welfare of that group to self and should be more willing to help VD victims than should subjects who experience increased self-focus 4 minutes before seeing the videotape. In addition, data from Michotte (1963) suggest that decreasing the time interval between the periods of increased self-focus and increased awareness of the distress of VD victims will increase self-attribution regardless of the order in which these periods of increased awareness occur.

With regard to the choice of VD victims, we should first note that studies on felt responsibility and helping behavior vary widely in terms of the number of help recipients, the proximity of the subjects to those people, and the extent to which situational cues provide justification for feeling personal responsibility. In the present experiment, we are particularly interested in determining

whether the attribution processes associated with the focus of attention affect felt responsibility and thus helping behavior when the subject is essentially removed from a fairly large group of persons in distress and has few situational cues that justify attribution of responsibility for that group to self. Selection of victims of VD as the target population represents a major part of the attempt to create these conditions.

Experiment 1

Method

Subjects. Subjects were 55 female undergraduates who volunteered for the study in partial fulfillment of a course requirement. Subjects were randomly assigned to four experimental conditions and one control condition and were run individually.

Procedure. Subjects were greeted by a female undergraduate experimenter and were seated in front of a television set. They were told that they were participating in an experiment designed to survey students' attitudes concerning certain social issues. The experimenter further explained that a short documentary videotape had been prepared to familiarize them with some of the facts concerning the particular social issue being investigated. Subjects were told that they would be asked to indicate their attitudes concerning the social issue by filling out a short questionnaire following presentation of the videotape. At this point, the experimenter explained that the study was also concerned with determining whether a simple audio or audio and visual presentation of factual material was more effective. Supposedly, some subjects would only hear the audio portion of the videotape, whereas others would be exposed to both the audio and the visual portions of the videotape. The rationale for interest in the effectiveness of various types of presentations was that previous experiments had failed to produce conclusive evidence on this point. All subjects were told that they were in the audio and visual condition.

After explaining the purpose of the experiment, the experimenter warned subjects not to be surprised if a live picture of themselves appeared on the TV screen at some time during the experiment. She indicated that the experiment would be submitted to the American Science Foundation for a grant and that the foundation wanted all grant proposals to include videotape recordings of all subjects and their exact experimental situations. If there were no questions, the experimenter told subjects she had to warm up the videotape machine for approximately 5 minutes, after which the documentary videotape would be shown and the questionnaire administered. The experimenter then moved behind a partition in the room in order to avoid contact with subjects prior to and after presentation of the videotape. After approximately 5 minutes had elapsed, a 2-minute videotape was shown. The videotape showed an adult male talking about victims of VD. He first presented statistics concerning the epidemic spread of venereal disease to a significant percentage of the population. He then discussed the various harmful physical and mental consequences that victims of venereal disease typically suffer. His presentation did not discuss the causes of VD or responsibility for the welfare of victims of VD, nor did it request any form of help for VD victims.

After viewing the videotape, subjects remained seated for an additional 5 minutes while the experimenter supposedly rewound the videotape and shut down the equipment. After 5 minutes had elapsed, the experimenter reentered the subject's portion of the cubicle and administered the dependent measures.

Time interval and before–after manipulations. In all conditions the experimenter first went behind the partition and activated some equipment that made noises audible to the subject. In the 4 minutes before condition, the experimenter then activated a TV camera positioned so that the subject's face appeared on the TV monitor. The subject was exposed to her image for 1 minute. After turning the camera off, the experimenter waited 4 minutes and then played the videotape. After showing the videotape, the experimenter activated other equipment that made noises audible to the subject, waited behind the partition for 5 minutes, and then administered the dependent measures. In the brief time interval before condition, the experimenter activated the equipment, waited for approximately 4 minutes, and then activated the TV camera focused on the subject. The subject was exposed to her image on the TV monitor for 1 minute. After the 1-minute exposure, the experimenter turned the camera off, delayed for 1 to 2 sec, and then presented the videotape. After exposure to the videotape, the experimenter waited 5 minutes and then administered the dependent measures. In the brief time interval after condition, the experimenter activated the equipment, waited for approximately 5 minutes, and then presented the videotape. The end of the videotape was followed by a 1- to 2-second delay. The experimenter then turned on the live TV camera, exposed the subject to her image on the TV monitor for 1 minute, waited for approximately 4 minutes, and administered the dependent measures. In the 4 minutes-after condition, the experimenter turned on the equipment, waited for 5 minutes, played the videotape, waited for 4 minutes, and then exposed the subject to her image on the TV monitor for 1 minute. The dependent measures were then administered. A control condition using similar instructions was also run. Subjects waited 5 minutes before and after seeing the videotape. However, no TV camera was visible to the subjects, and the subjects were never exposed to a live image of their faces on the TV monitor.

Table 1
Mean Attribution of Responsibility for Victims of VD to Self

Condition	Immediate	4-minute interval
Before	9.0	6.9
After	10.27	7.9
Control	6.5	

Note. The larger the number, the greater the attribution to responsibility to self. For each condition, $n = 11$. VD = venereal disease.

Dependent measures. Five minutes after the videotape ended, subjects were given a questionnaire to fill out. The questionnaire included items concerning the content and effectiveness of the videotaped presentation. It also included questions designed to assess subjects' feelings of responsibility for the welfare of VD victims and willingness to help victims of VD. These questions were the following:

1. To what extent would you say that the failure to control the current VD epidemic is due to the public's, including your own, lack of concern rather than to the VD victim himself?
2. To what extent would you be willing to take a 1-hour course dealing with the prevention and treatment of VD and then conduct two half-hour educational sessions with groups of college freshmen?
3. A VD clinic exists in the college community but is underfinanced and greatly understaffed. How much time per week would you be willing to spend doing volunteer work at the clinic?
4. How large a financial contribution would you be willing to make to the National Center for the Prevention of VD?

All questions were accompanied by 15-point scales anchored at both ends with appropriate positive and negative labels. After subjects had completed the questionnaire, the experimenter checked for suspicion and then revealed the true nature of the experiment and experimental procedures.

Results

An analysis of data obtained from questions concerning the content and effectiveness of the videotaped presentation was carried out to determine if the experimental manipulations affected the subject's memory of the information presented on the tape or her impression of the effectiveness of the presentation. No significant differences between conditions were found for content or for effectiveness ($F < 1$ in all cases). In addition, no differences between the control condition and any of the experimental conditions were found on these measures ($F < 1$ in all cases).

The first experimental hypothesis suggests that a person should tend to see self as responsible for the welfare of people in distress to the extent that a brief time interval separates the periods of increased self-focus and increased awareness of distressed persons. In addition, this effect should occur regardless of the order in which increased self-focus and increased awareness of the distressed others occur. An analysis of the attribution of responsibility to self data (Table 1) is consistent with this prediction. Subjects in the brief time interval conditions felt more personal responsibility for the welfare of VD victims than did subjects in the 4-minute time interval conditions, $F(1, 41) = 5.01$, $p < .05$. There was no effect for before–after or any interaction between before–after and time interval ($F < 1$) in both cases. A comparison between the brief time interval conditions and the control condition evidenced the presence of a reliable difference, $F(1, 50) = 7.01$, $p < .05$. A similar comparison between the 4-minute time interval conditions and the control did not reveal the presence of a significant difference ($F < 1$).

The second experimental hypothesis suggests that focusing on self immediately before or after awareness of the distress of others is increased should result in increased willingness to help those persons. The mean responses to each of the questions designed to measure willingness to help victims of VD are presented in Table 2. Responses to these questions were highly correlated (rs ranging from .59 to .76) and were summed for purposes of analysis. The results of this analysis indicated that subjects in the brief time interval conditions expressed greater overall willingness to help victims of VD than did subjects in the 4-minute time interval conditions, $F(1, 41) = 6.41$, $p < .05$. No other significant main effects or interactions were found. Additional comparisons indicated that subjects in the brief time interval conditions were more willing to help than were subjects in the control condition, $F(1, 50) = 4.20$, $p < .05$, whereas subjects in the 4-minute interval conditions were not ($F < 1$).

Table 2
Mean Willingness to Help Victims of VD

Item	No interval before	No interval after	4-minute interval before	4-minute interval after	Control
Teach class	11.2	11.2	8.5	7.9	7.0
Volunteer work at clinic	7.6	8.9	7.6	6.0	8.2
Personal contribution	6.9	7.7	3.3	6.6	5.2
Combined	25.7	27.8	19.4	20.5	20.4

Note. Numbers represent means for each condition. The higher the number, the greater the willingness to help.

Discussion

The results from Experiment 1 clearly support both experimental hypotheses. Subjects who focused on self immediately before or after the plight of VD victims was made salient attributed greater responsibility for the welfare of that group to self and indicated greater willingness to expend time, effort, and money to help VD victims than did subjects who focused on self 4 minutes before or after seeing the videotape on VD victims. Comparisons between the experimental conditions and control condition indicate that these main effects were due to increases in attribution of responsibility to self and willingness to help in the brief time interval conditions rather than to any decrease in the magnitude of those responses in the 4-minute time interval conditions.

Alternate explanations. It might be argued that putting the subject's image on the screen immediately before or after the videotape had been shown caused subjects to suspect that the experimenter wanted them to feel personally responsible for victims of the VD epidemic. This argument is challenged by the results in the 4-minute time interval/after condition. Subjects in this condition saw their image immediately before they filled out the dependent measures. If subjects were susceptible to the belief, "The experimenter is trying to get me to feel personally responsible for the welfare of victims of VD by putting my face on TV," it seems reasonable that introducing the subjects' images immediately before the dependent measures were administered would be just as likely to make them suspicious about the motives of the experimenter as would introducing their images before or after the videotape. Since subjects in the 4-minute time interval/after condition did not differ from subjects in the control condition, it would be difficult to argue that the experimental results were due to experimental demand.

Aside from an experimental demand explanation, it might be argued that increasing subjects' self-focus in the brief time interval conditions affected helping behavior by increasing their efforts to conform to a generalized norm or standard of helping others (Wicklund, 1975). However, if increasing self-focus affected helping behavior via a direct self-evaluative mechanism (Duval & Wicklund, 1972), it seems reasonable to expect increased willingness to help when self-focus was increased immediately before measures of helping were taken, that is, in the 4-minute time interval/after condition. Since there is no evidence of increased willingness to help in this condition, we must conclude that the self-attribution interpretation of the obtained effects, at least under these experimental conditions, must be given substantial consideration.

Experiment 2

The data from Experiment 1 are consistent with the two experimental hypotheses but do raise several issues. Since the self-attribution measure separated VD victims and subjects as members of the general public into two discrete groups that might be responsible for victims of the VD epidemic, it is conceivable that subjects actually considered themselves as separate from the general public when responding to this question. To resolve this interpretational ambiguity,

the attribution-of-responsibility-to-self measure in Experiment 2 was more direct and specifically asked subjects to determine the extent to which they were responsible for the people in question.

Second, to provide evidence concerning the generality of the proposed relationship between self-focus, felt responsibility, and helping behavior and to demonstrate the conceptual replicability of the results obtained in Experiment 1, Experiment 2 used a different technique to increase self-focus and presented a different population as potential help recipients. To increase self-focus, subjects were asked to fill out a biographical questionnaire, a procedure that should increase self-focus (Duval & Wicklund, 1972) as effectively as a TV camera. The target population consisted of poverty-stricken Latin Americans rather than VD victims.

Third, we have assumed that increasing self-focus affects felt responsibility for a specific group only if awareness of that group's distress is increased immediately before or after self-focus is increased. This may not be the case. Increasing self-focus a few minutes before measuring felt responsibility for a particular group of distressed persons may increase felt responsibility for that group even when awareness of the group's distress has not been increased. To test this possibility, Experiment 2 included a control condition in which subjects filled out the biographical questionnaire but were not exposed to any material designed to increase awareness of poverty-stricken Latin Americans prior to administration of the dependent measures.

Finally, the inclusion of the 4-minute time interval/after condition in Experiment 1 renders an experimental demand or a direct self-evaluation interpretation of the obtained results unlikely. On the other hand, increasing self-focus typically causes attitudes and norms to change in the direction of any relevant and positive reference group's majority position (Duval, 1976; Duval & Wicklund, 1972; Wicklund & Duval, 1971). The existence of this effect suggests that juxtaposing the subject's image and material related to victims of VD may have caused the subject's attitudes and/or norms concerning victims of VD to change in a direction dictating more helping behavior. From this point of view, the increased willingness to help observed in the brief time interval conditions of Experiment 1 might have been due to changes in attitudes and/or norms rather than to the differences in felt responsibility. We view this as an unlikely possibility, since any mention of other people's attitudes and norms regarding victims of VD was carefully avoided. Nevertheless, it is a plausible alternative explanation for the results in Experiment 1 that cannot be ruled out. In fact, no study on felt responsibility and helping behavior has determined if the manipulation of felt responsibility also affects attitudes and norms. Thus, in Experiment 2, the dependent measures included two items designed to measure subjects' attitudes and norms toward the target population, poverty-stricken Latin Americans.

The hypotheses of Experiment 2 were essentially the same as those of Experiment 1. To test these hypotheses, subjects filled out a biographical questionnaire either 4 minutes before or immediately before seeing a videotape on poverty-stricken Latin Americans. It was predicted that subjects in the brief time interval condition would feel more responsibility for and would be more willing to help poverty-stricken Latin Americans than would subjects in the 4-minute time interval condition.

Method

Subjects. Subjects were 55 female undergraduates who volunteered for the study in partial fulfillment of a course requirement. Subjects were randomly assigned to two experimental and three control conditions and were run individually.

Procedure. Subjects were greeted by a male experimenter and were seated in front of a television set. From this point on, the experimenter's explanations of the purpose of the study and the subject's role in the study were similar to the explanations given to subjects in Experiment 1. After the purpose of the experiment had been explained, subjects were told that they would also be asked to fill out a short biographical questionnaire. Subjects were told that this information was needed in order to determine whether participants in the survey were all relatively homogeneous with regard to personality and background. After these instructions, the experimenter's actions were essentially the same as those in Experiment 1.

The 10-minute documentary videotape was composed of segments taken from a film called *Highland Indians of Peru*. These segments consisted of fairly impactful scenes depicting the urban and rural poor of Peru and were accompanied by a spoken commentary. However, the videotape and commentary did not suggest that the film referred to a particular people or country and treated the scenes as though they were characteristic of large portions of the Latin American population. In addition, the videotape did not discuss the causes of poverty in Latin America or responsibility for this situation, nor did it request any form of help for the Latin American poor.

After viewing the videotape, subjects remained seated for an additional 5 minutes while the experimenter supposedly rewound the videotape and shut down the equipment. After the 5-minute waiting period had elapsed, the experimenter reentered the subject's portion of the cubicle and administered the dependent measures.

Time interval manipulation. In the 4-minute time interval condition, the experimenter went behind the partition, reentered the cubicle, and handed the subject a biographical questionnaire saying: "Please take about a minute to fill this out, and let me know when you've finished." After the subject had finished the questionnaire and had returned it to the experimenter, the experimenter waited for 4 minutes. He then played the videotape about poverty-stricken Latin Americans on the subject's TV monitor. In the brief time interval condition, the experimenter turned on the equipment, waited for 4 minutes, and then asked the subject to fill out the biographical questionnaire. After the subject had finished the questionnaire and had returned it, the experimenter played the documentary videotape on the subject's TV monitor.

Biographical questionnaire. The biographical questionnaire was designed to require subjects to think about themselves as objects but purposely avoided asking any questions that might sensitize them to responsibility for the poor in Latin America. The items included on the questionnaire were the following: (a) age; (b) sex; (c) scholastic major; (d) intended area of employment after completing college; (e) hobbies; (f) briefly describe your physical characteristics (size, weight, looks, etc.); (g) briefly describe your most unique characteristic. The item concerning uniqueness was considered the critical question in terms of increasing self-focus, since data (Duval, 1976; Duval & Duval, Note 1; Duval & Siegel, Note 2) indicate that increasing the salience of a person's novelty as an object in the world increases the tendency for attention to focus on self.

Control conditions. In the no-biographical-questionnaire control condition, the experimenter followed the same procedures used in the experimental conditions, except that the biographical questionnaire was not mentioned and the subject did not, in fact, fill out such a questionnaire. The videotape on poverty in Latin America was shown approximately 5 minutes after the experimenter's initial instructions were completed. In the no-videotape control condition, the subject filled out a biographical questionnaire but did not see the videotape concerning poverty-stricken Latin Americans. The biographical questionnaire was administered approximately 4 minutes after the experimenter had completed his initial instructions. In the no-biographical-questionnaire/no-videotape control condition, the subjects neither filled out the biographical questionnaire nor saw the videotape on poverty in Latin America. In all control conditions, the time interval between the end of the experimenter's initial instructions and administration of the dependent measures was approximately the same as the corresponding time interval in the experimental conditions.

Dependent measures. The dependent measures included the following items, listed in order of presentation:

1. The level of poverty suffered by many Latin Americans is totally undesirable.
2. The level of poverty suffered by many Latin Americans ought to be substantially reduced.
3. To what extent do you feel any personal responsibility for the poverty-stricken people of Latin America?
4. To what extent would you be willing to take a 1-hour course dealing with poverty in Latin America and then conduct two half-hour educational sessions with groups of college freshman?
5. Several agencies dealing with poverty in Latin America exist in Los Angeles but are understaffed. How much time per week would you be willing to spend doing volunteer work at one of these agencies?
6. How large a personal financial contribution would you be willing to make to the Agency for Latin American Development?

All questions were accompanied by 15-point scales anchored with the appropriate positive and negative levels. After subjects had completed the questionnaire, the experimenter checked for suspicion and informed the subject of the actual purpose of the experiment and experimental procedures.

Results

Data from Experiment 1 indicated that subjects in the brief time interval conditions attributed more responsibility for victims of VD to the general public including self. This was interpreted as reflecting greater attribution of responsibility to self. As was mentioned, however, this measure could have reflected the subject's attribution of responsibility to the general public but not to self. Experiment 2 attempted to resolve this question by using a more directly phrased question concerning the subject's attribution of

Table 3
Mean Attributed Responsibility and Willingness to Help

Item	Brief time interval	4-minute time interval	No bio control	No video control	No bio control/no video control
Felt responsibility	5.21_a	3.06_b	2.81_b	2.54_b	3.19_b
Teach class	8.31	5.10	4.4	3.46	3.77
Volunteer work at clinic	7.79	3.57	4.32	4.42	3.58
Personal contribution	6.24	3.29	4.00	3.59	4.20
Combined	22.34_a	11.96_b	12.72_b	11.45_b	11.65_b

Note. For each condition, $n = 11$. Numbers represent means for each condition. The higher the number, the greater the responsibility attributed to self and willingness to help. Means with similar subscripts do not differ.

responsibility to self. As predicted (see Table 3), subjects who completed the biographical questionnaire immediately before seeing the documentary videotape on poverty-stricken Latin Americans attributed more responsibility to self than did subjects who completed the questionnaire 4 minutes before viewing the videotape, $t(20) = 2.57$, $p < .02$. An additional analysis using the Newman–Keuls procedure indicated greater attributed self-responsibility in the brief time interval condition than in any other condition ($p < .05$).

Data from Experiment 2 also replicate the findings in Experiment 1 with regard to willingness to help the target population (Table 3). Subjects in the brief time interval condition exhibited greater willingness to expend time, effort, and money (*r*s ranged between .76 and .82 and were summed for analysis) to help the poor of Latin America than did subjects in the 4-minute time interval condition, $t(20) = 2.66$, $p < .02$. An additional analysis using the Newman–Keuls procedure indicated greater willingness to help in the brief time interval condition than in any other condition ($p < .05$).

Experiment 2 was also designed to determine whether the experimental manipulation of self-focus affected subjects' attitudes and/or norms concerning poverty-stricken Latin Americans. As is evident in Table 4, expressed attitudes and norms did not differ between conditions ($p > .20$).

Conclusions

A number of conclusions regarding the relationships between self-focus, attribution of responsibility to self, and helping behavior can be drawn from the results obtained in Experiments 1 and 2. First, it appears that increasing self-focus increases self-attribution for a situation or event. However, this relationship obtains only to the extent that the periods of increased self-focus and awareness of the situation or event are separated by a relatively short time interval. These results suggest that the unit formation principle of temporal proximity does apply to the time interval that separates periods of increased self-focus and increased awareness of situations and events, as well as to the time interval that separates the actual presence

Table 4
Mean Attitude and Norm Regarding Poverty in Latin America

Level of poverty	Immediately before	4 minutes before	No bio control	No video control	No bio control/no video control
Totally undesirable	13.34	12.86	13.14	10.40	9.82
Ought to be substantially reduced	12.85	13.22	14.67	12.21	13.74

Note. Numbers represent means for each condition. The higher the number, the stronger the attitude or norm.

or occurrence of agents, situations, and events. In and of itself, this conclusion has obvious implications for dealing with both the theoretical and empirical relationship between self-focus and self-attribution.

Second, juxtaposing self-focus and a salient group of distressed persons increases willingness to expend time, effort, and money to help that group. The failure to find increased self-attribution and willingness to help in the 4-minute interval/after condition of Experiment 1 suggests that an experimental demand or a direct self-evaluation interpretation (Duval & Wicklund, 1972) of this relationship is not highly plausible. In Experiment 2, increasing self-focus produced differences in felt responsibility for and willingness to help the poor in Latin America without differentially affecting subjects' attitudes and norms toward the target population and their difficulties. These data suggest that the effect of self-focus on helping behavior is not caused by change in attitudes and/or norms. Having ruled out these alternative explanations, we conclude that juxtaposing self-focus and a salient group of distressed persons affects helping behavior by increasing felt responsibility for the welfare of that group. However, this conclusion must be tempered by the results obtained by Federoff and Harvey (1976), which suggest that some as yet unidentified variable may affect the relationship between self-focus and internal versus external attribution for a negative event.

The obtained relationship between self-focus and helping behavior has other implications for the study of helping behavior. Specifically, any conditions that affect self-focus when distressed others are salient should affect felt responsibility and thus helping behavior. Since the focus of attention is generally attracted to "important" or "novel" stimuli, conditions that increase or decrease the relative situational importance or novelty of an individual when distressed others are salient should increase or decrease that person's level of self-focus, felt responsibility, and tendency to help the needy others. The relevance of this proposition for the general study of helping behavior has been demonstrated in a recent experiment. Using the notion that the novelty of two interacting groups is affected by the relative number of people in each group (Duval, 1976; Duval & Wicklund, 1972), Wegner and Schaefer (1978) hypothesized that increasing the number of subjects who could help a single victim should decrease subjects' levels of situational novelty, self-focus, and helping behavior. Similarly, increasing the number of victims confronting a single subject should increase the subject's level of situational novelty, self-focus, and helping behavior. These hypotheses were confirmed. Although felt responsibility was not measured, subjects run in groups of three tended to focus on self and to help a needy person less than did subjects run singly; individual subjects confronted with three victims focused on self and helped those victims more than did individual subjects faced with a single victim.

The novelty/self-focus/felt responsibility/helping behavior relationship may also apply to the relationship between distinctive suitability (Schwartz, 1970), dependency (Berkowitz, 1972), and helping. A person who is one of a "limited and uniquely qualified" group of potential helpers (high distinctive suitability) would be more novel in that situation than a person who is merely one of many people who could help (low distinctive suitability, Schwartz, 1970). To the extent that a person is depended on by others, that person is defined as uniquely important with respect to helping others. Thus, increasing distinctive suitability or dependency may increase a person's tendency to help others in distress because those manipulations affect the individual's level of situational novelty or importance, self-focus, felt responsibility and, thus, helping behavior.

In summary, research has found a strong empirical relationship between felt responsibility and helping behavior. The present research demonstrates that juxtaposing self-focus with a salient group of needy others increases felt responsibility for and willingness to help those others. We have suggested that the effects of distinctive suitability, dependency, and relative number of potential helpers and victims on helping behavior may be mediated by self-focus and attribution of responsibility to self. Thus, the self-focus/felt responsibility relationship may have sub-

stantial significance for the general study of helping behavior.

Sex Role Identity and Its Relationships to Sex Role Attributes and Sex Role Stereotypes

Michael D. Storms
University of Kansas

Kagan's and Kohlberg's theories of sex role identity are examined in this paper. Both theories premise relationships among an individual's sex role identity, his/her perception of sex role stereotypes, and his/her own masculine and feminine sex role attributes, but the theories specify different patterns of correlations among these variables. Kagan's theory views sex role identity as the product of the mutual influence of stereotypes and attributes, whereas Kohlberg's theory posits sex role attributes as the product of stereotypes and identity. College men and women were administered measures of each variable including the Personal Attributes Questionnaire (PAQ; Spence and Helmreich), modified versions of the PAQ to measure stereotypes of men and women, and a measure of sex role identity developed by the present author. The results indicated an overall relationship between sex role identity and the other two variables. Beyond that, the results generally supported Kohlberg's theory over Kagan's. Significant correlations were found where Kohlberg's theory would predict a relationship—between sex role stereotypes and sex role attributes. Nonsignificant correlations were found where Kagan's theory would predict a relationship—between sex role stereotypes and sex role identity. These results are compared to earlier findings by Spence, Helmreich, and Stapp, and questions are raised about the psychological constructs underlying measures of sex role attributes.

Over the past decade, researchers have amassed considerable data on sex role stereotypes (e.g., Rosenkrantz et al., 1968) and masculine and feminine sex role attributes (e.g., Bem, 1974; Spence & Helmreich, 1978). Relatively less attention has been paid to self-concepts of masculinity and femininity—that is, to sex role identity. Although sex role identity has existed as a theoretical construct for some time (Kagan, 1964; Kohlberg, 1966), there has been no widely accepted measure of sex role identity and little research on its relationships to sex role attributes and sex role stereotypes.

Kagan (1964) and Kohlberg (1966) have both defined sex role identity as an acquired self-concept of being masculine or feminine, and they have proposed that sex role identity is closely related to sex role stereotypes and sex role attributes. The two theorists differ sharply, however, about the causal structure of these relationships. Kagan postulates that sex role identity is the product of differences between individuals' sex role attributes and their perceptions of sex role stereotypes; Kohlberg believes that sex role identity is the cause of those differences. Figure 1 illustrates the causal structure of these two theories.

Specifically, Kagan (1964) theorizes that individuals compare their own attributes against sex role stereotypes to arrive at a relativistic self-concept of their sex role identity. In Kagan's (1964) words:

Sex-role identity represents the degree to which an

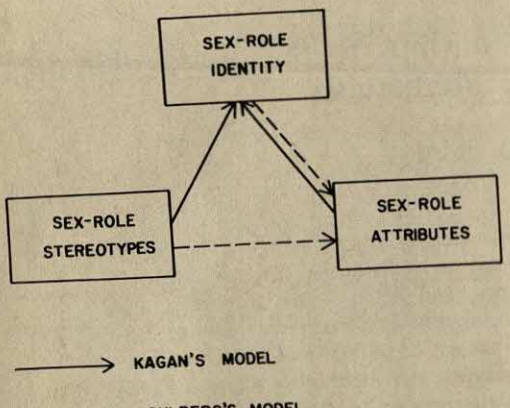

Figure 1. Kagan's (1964) and Kohlberg's (1966) models of the relationships among sex role identity, attributes, and stereotypes.

individual regards himself as masculine or feminine. . . . The degree of match or mismatch between the sex-role standards of the culture and an individual's assessment of his own overt and covert attributes provides him with a partial answer to the question, "How masculine (feminine) am I?" (p. 144)

In short, Kagan views sex role identity as the product of sex role stereotypes and sex role attributes.

In contrast, Kohlberg (1966) asserts that sex role identity is firmly established early in life and thereafter serves to mediate the influence of sex role stereotypes on the individual's development of sex role attributes. Sex role identity guides the individual's attachment to, evaluation of, and desire to emulate sex role prototypes (specific adult role models) and sex role stereotypes (abstract role models). Sex role attributes, according to Kohlberg's theory, are the product of the individual's sex role identity and perception of sex role stereotypes.

The theories described above lead to many similar hypotheses about the relationships among sex role identity, sex role stereotypes, and sex role attributes. Both theories predict a multiple correlation among the three sex role variables—knowing any two of the variables should enhance prediction of the third. Both theories also predict a correlation between sex role attributes and sex role identity, although for opposite reasons—either because attributes influence identity (Kagan) or because identity influences attributes (Kohlberg).

The two theories differ most noticeably in their hypotheses about the relationships between sex role stereotypes and the other two variables. According to Kagan's theory, sex role stereotypes and sex role attributes interact to determine sex role identity. Thus, Kagan's theory predicts a correlation between stereotypes and identity but not (necessarily) a correlation between stereotypes and attributes. Conversely, according to Kohlberg's theory, sex role stereotypes and sex role identity interact to determine sex role attributes. Kohlberg's theory predicts a correlation between stereotypes and attributes but not (necessarily) between stereotypes and identity.

The relationship between sex role stereotypes and sex role attributes has already been investigated in a study by Spence, Helmreich, and Stapp (1975). Briefly, they found no correlation between these two variables—a finding that would support Kagan's theory and contradict Kohlberg's. Unfortunately, there are several methodological problems with the Spence et al. study that cast some doubt on the relevance of their data to the present discussion. Examination of these problems will require a detailed review of the procedures used.

The main purpose of Spence, Helmreich, and Stapp's (1975) study was to introduce a new measure of sex role attributes, the Personal Attributes Questionnaire (PAQ). Spence et al. created the PAQ to measure stable, underlying personality traits associated with masculinity and femininity, but they were also aware of a possible alternative interpretation of their scale. Spence et al. noted that items on masculinity–femininity scales (including the PAQ) are usually adopted from lists of sex role stereotypes. Thus, an individual's endorsement of a particular item could merely indicate his/her knowledge of and identification with the corresponding stereotype and not an accurate reflection of his/her actual traits.

Spence, Helmreich, and Stapp (1975) proposed a test of the competing stereotype interpretation of the PAQ. They reasoned that according to the stereotype hypothesis, people's self-ratings on masculinity and feminin-

ity scales should be correlated with their perceptions of sex role stereotypes. For example, people who believe that a particular trait is very characteristic of their sex in general should rate themselves higher on that trait than will people who think the trait is less characteristic of their sex. In contrast, according to the trait hypothesis, self-ratings reflect genuine attributes of individuals independent of their beliefs about sex roles, and the two should not be correlated. People who have more of a trait should rate themselves higher on that trait independently of their beliefs about how much of the trait others of their sex have.

Spence, Helmreich, and Stapp (1975) selected 55 traits that pretest subjects had rated as more typical of one sex than the other. These items were sorted into three scales—two independent masculinity (M) and femininity (F) scales and a third, bipolar masculinity–femininity (M–F) scale. Male and female college students first rated themselves on each of the 55 items, then rated each item for the typical male or female. Eighteen correlations were generated by comparing male and female subjects' self-ratings on each scale to their stereotype ratings on all three scales. Finding only 5 of these 18 correlations statistically significant, Spence et al. rejected the stereotype hypothesis and concluded that the PAQ measures genuine traits. In the present context, these results could also be interpreted as evidence against Kohlberg's theory of sex role identity, which also predicts a correlation between sex role stereotypes and sex role attributes.

Unfortunately, there are at least three methodological problems with the Spence, Helmreich, and Stapp (1975) study that cast doubt on their conclusions. First, Spence et al. used different item formats for subjects' stereotype ratings than for their self-ratings. For self-ratings, subjects were presented with bipolar items (e.g., *very passive* to *very active*), whereas for stereotype ratings subjects were presented with single labels (e.g., *active*). These two formats could have created different psychological dimensions for the subjects; a subject who saw only the word *active* may have assumed that the intended opposite was *inactive* rather than *passive*. Thus, subjects may have rated stereotypes along dimensions somewhat different from those they used in rating themselves. That would have greatly reduced any possibility of obtaining correlations between the attribute and stereotype ratings.

A second problem was created by the particular type of rating scale that followed each stereotype item. Each single label was followed by a bipolar, unidimensional scale ranging from *much more characteristic of the male* to *much more characteristic of the female*. The problem with using unidimensional scales to measure stereotypes is that ratings in the middle of such scales are ambiguous. A middle rating could mean that the trait was seen as either highly characteristic of both sexes or not characteristic of either sex. That ambiguity in turn could have reduced correlations between attribute and stereotype ratings. According to the stereotype hypothesis, subjects who thought a particular trait highly characteristic of both sexes would have rated the trait in the middle of the stereotype scale, but they would have rated themselves high on the trait. On the other hand, subjects who saw the trait as uncharacteristic of either sex would also have rated the trait in the middle of the stereotype scale, but they would have rated themselves low on the trait. These two possibilities would cancel each other out and artifactually lower the correlation between attribute and stereotype ratings.

A final problem with Spence, Helmreich, and Stapp's (1975) study concerns the 18 correlations they presented as tests of the stereotype hypothesis. The 18 correlations were generated by comparing attribute ratings on each of three different scales to stereotype ratings on all three scales separately for each sex. But two of the three attribute scales (the M scale and the F scale) were theoretically designed and empirically shown to be uncorrelated with each other. If attribute ratings alone were not expected to correlate between scales, it was inappropriate to expect attribute ratings and stereotype ratings to correlate between scales. Eliminating these cross-scale comparisons, only 6 of the 18 possible correlations actually provide a valid test of the

stereotype hypothesis—namely, self-ratings on each scale compared to stereotype ratings only on the *same scale*, calculated separately for each sex on each scale. Of these 6 correlations, 3 were significant and in the predicted direction. Viewed thus, Spence, Helmreich, and Stapp's (1975) results provide highly equivocal evidence about the stereotype hypothesis and not definitive evidence against it. It would also be unfair to rule against Kohlberg's theory of sex role identity on the basis of those results.

The present study was designed to investigate Kagan's (1964) and Kohlberg's (1966) models of sex role identity, using a paradigm similar to Spence, Helmreich and Stapp's (1975) but with several methodological improvements. First, subjects were asked to make attribute ratings and stereotype ratings on identical sets of bipolar items. Second, subjects' stereotypes were measured by taking separate ratings of the typical male and the typical female on all items. Third, attribute ratings and stereotype ratings were compared only within each scale and not between scales. Finally, a measure of sex role identity was included.

Method

Subjects and Procedure

One hundred four male and 110 female students in introductory social psychology at a midwestern state university completed a battery of four instruments described below. The batteries were completed during one class period at the beginning of the semester. Subjects' responses were voluntary and anonymous. The instructor in the course debriefed the class and presented a lecture based on the results later in the semester.

Instruments

Because no widely accepted measure of sex role identity presently exists, a new instrument was designed for the present study.[1] In keeping with the definition of sex role identity as "a global self-concept of one's masculinity and femininity," the Sex Role Identity Scale (SRIS) was written to include extremely simple, face-valid queries about self-concept. Subjects were asked to rate themselves on three masculine and three feminine items: "How masculine (feminine) is your personality?" "How masculine (feminine) do you act, appear, and come across to others?" and "In general, how masculine (feminine) do you think you are?" Each item was followed by a 31-point scale with the endpoints labeled *not at all masculine (feminine)* (scored as 0) to *extremely masculine (feminine)* (scored as 30).

Subjects' sex role attributes were measured by Spence and Helmreich's (1978) Personal Attributes Questionnaire, a shortened version of the Spence, Helmreich, and Stapp (1975) measure described earlier. It contains 24 of the original 55 items, still categorized into three subscales—an M scale, an F scale, and a unidimensional M–F scale. Each scale contains 8 items; each item is scored from 0 to 4; and total scores on each scale can range from 0 to 32. Higher values indicate greater endorsement of M items, F items, or the masculine pole of M–F items.

Subjects' stereotypes were measured by two modified versions of the PAQ. One questionnaire asked subjects to rate the "typical male," and one asked subjects to rate the "typical female." Thus, stereotype ratings for each sex were gathered separately using exactly the same scales as the self-ratings. The same scoring system was used for each stereotype scale as was used for the corresponding self-rating scale.

The order of the four questionnaires in the battery was randomized across subjects, except that the two stereotype questionnaires always appeared together.

Results

The Sex Role Identity Scale

Since a new measure of sex role identity was designed for this study, its psychometric properties were examined first. The scale showed strong internal consistency: the three masculine identity items intercorrelated positively better than .66 for men and .68 for women (all $ps < .001$), and the three feminine identity items intercorrelated positively better than .80 for men and .70 for women (all $ps < .001$). More important, despite all the evidence of multidimensionality in people's sex role attributes (Bem, 1974; Constantinople,

[1] Two researchers have designed instruments that may appear related to sex role identity. First, Stein (1971) has measured *sex role preference*, which may share some conceptual meaning with sex role identity. The two concepts are not identical, however. Logically, one can prefer to have sex role characteristics that differ from one's present sex role self-concept. Second, Heilbrun (1976) has published a measure called "sex role identification"; however, the composition and use of that instrument suggest that it measures specific sex role attributes rather than a global sex role self-concept.

Table 1
Means, Standard Deviations, and p *Values for Male–Female Differences on all Measures*

Scale	Men		Women		
	M	*SD*	*M*	*SD*	*p*
Sex role identity	24.43	4.25	7.86	5.26	.001
Attribute self-ratings					
M	22.58	4.78	20.15	4.30	.001
F	21.56	4.41	23.92	3.38	.001
M–F	16.77	4.54	12.87	4.07	.001
Stereotype ratings of men					
M	24.68	3.96	24.08	3.80	*ns*
F	17.10	5.00	17.22	4.76	*ns*
M–F	20.53	4.32	19.83	4.17	*ns*
Stereotype ratings of women					
M	15.75	4.13	16.94	4.99	*ns*
F	24.70	4.10	24.18	3.69	*ns*
M–F	9.09	3.79	10.84	3.95	.001

Note. Higher values indicate greater endorsement of masculine items on M scales, of feminine items on F scales, and of the masculine pole of items on the M–F scales and the Sex Role Identity Scale. For men, $n = 104$. For women, $n = 110$. M = masculine. F = feminine.

1973; Spence & Helmreich, 1978), subjects in this study conceptualized their sex role identities along a single dimension. Masculine identity items correlated negatively with feminine identity items better than −.64 for men and −.74 for women (both $ps < .001$). Therefore, the six items were combined by scoring the three feminine items in the opposite direction from the three masculine items, summing, and dividing by six—thus yielding a 31-point, bipolar sex role identity score ranging from 30 (most masculine/least feminine) to 0 (least masculine/most feminine).

Sex Differences on All Measures

All of the hypotheses in the present study presume the existence of sex-of-subject differences in sex role identity and attributes and sex-of-target differences in sex role stereotypes. Table 1 illustrates these differences. Male and female subjects reported not only significant but extremely large differences on the measure of sex role identity, with means of 24.4 and 7.9, respectively, $p < .001$. Males and females also reported significant differences on all three subscales of the sex role attributes measure, the PAQ. Men reported higher self-ratings on the M scale and the bipolar M–F scale, whereas women reported higher self-ratings on the F scale.

Although men and women differed in their attribute and identity self-ratings, they agreed in their stereotypes about the typical man and the typical woman. Men and women differed in their stereotype ratings in only one instance: Women rated the typical woman higher on the M–F scale. Men and women also agreed on the differences between the typical man and the typical woman, as can be seen by making vertical comparisons between the two stereotype scales in Table 1. Both sexes rated the typical man higher on the M scale and the M–F scale and rated the typical woman higher on the F scale (all $ps < .001$). In short, all of the instruments produced results consistent with past research and consistent with the assumptions underlying this study.

Correlations Among Measures

Correlations among identity, attribute, and stereotype ratings are presented in Table 2. Before discussing these correlations, I should explain the structure of Table 2. As argued earlier, it is appropriate to consider only those correlations occurring within each subscale of

Table 2
Correlations Among Sex Role Identity, Sex Role Stereotypes, and Sex Role Attributes for Men and Women

Correlation	Attribute/stereotype scales					
	Men			Women		
	M	F	M–F	M	F	M–F
Multiple						
$I = AS$	.43***	.20*	.34***	.23**	.42***	.27**
$A = IS$	.53***	.19*	.39***	.31***	.43***	.41***
$S = AI$	.39***	.26**	.21*	.35***	.22*	.33***
Zero-order and partial						
AI	.43***	−.05	.34***	.07	−.41***	.27**
$AI–S$	.39***	−.08	.34***	.13	−.39***	.27**
SI	.19*	.19*	.06	−.19*	−.17*	.05
$SI–A$	.04	.19*	−.02	−.22*	−.10	−.16
SA	.39***	.17*	.21*	.28***	.20*	.33***
$SA–I$	.34***	.19*	.20*	.30***	.14	.33***

Note. Variables are abbreviated: A = attributes, S = stereotypes, and I identity. In the multiple correlations the first variable is the dependent variable. In the rest of the table, two variable initials indicate a zero-order correlation and three variable initials indicate a partial correlation between the first two variables controlling for the third variable. For men, $n = 104$. For women, $n = 110$. An equals sign indicates multiple correlations, whereas a dash indicates partial correlations. M = masculine. F = feminine.
* $p < .05$. ** $p < .01$. *** $p < .001$.

the PAQ and not between scales. Since every correlation in this study involved one or both of the subscaled instruments (i.e., the self-rating version of the PAQ and/or the stereotype-rating version), each correlation was calculated six times, once for each subscale for each sex—thus yielding the six columns in Table 2. The hypotheses were tested by examining the three multiple correlations among the three variables, the three zero-order correlations between each pair of variables, and the three partial correlations between each pair of variables controlling for the third variable—thus yielding the nine rows in Table 2.[2]

The multiple correlations among sex role identity, sex role attributes, and sex role stereotypes are presented first in Table 2. Both sex role identity theories presume that sex role identity is involved in a casual structure with sex role attributes and sex role stereotypes. For Kagan, sex role identity is the product of this structure; for Kohlberg, sex role attributes are the product. Kagan's theory thus leads one to examine the multiple correlation with sex role identity as the dependent variable. Kohlberg's theory is more appropriately tested with sex role attributes as the dependent variable. In fact, both of those multiple correlations, and even the correlation with stereotypes as the dependent variable, were significant for both sexes on each of the three attribute/stereotype subscales, as seen in the top three rows of Table 2. One might notice that Kohlberg's correlations (second row) accounted for somewhat more variance than Kagan's correlations (first row) in four of the six comparisons—10% more in two instances (men on the M scale and women on the M–F scale) and about 5% more in two instances (men on the M–F scale and women on the M scale). This is far from a crucial test between the two theories, however; both theories are essentially supported by these results.

[2] Many other analyses were performed on these data, including all possible part correlations, correlations of the differences between two variables and the third, and correlations of the differences between male and female stereotypes and the other variables. All of these auxiliary analyses produced results entirely consistent with the main analyses presented in Table 2 and so are not reported here.

The two theories also agree that significant correlations should obtain between sex role attributes and sex role identity (although they disagree about the causal mechanisms that should produce these correlations). Given the direction in which the various scales are coded, these correlations should be positive for both sexes on the M and M–F subscales and negative on the F subscale. The correlations presented in the fourth and fifth rows of Table 2 strongly supported both theories in four of the six comparisons. For both the zero-order and the partial correlations, men reported a significant correspondence between their sex role identity and their sex role attributes on the M and M–F scales of the PAQ. Women reported a similar correlation between their sex role identity and sex role attributes on the F scale and the M–F scale. Thus it appears that sex role identity was related to sex role attributes, but only on those scales that were most appropriate for the subject's own sex—that is, the masculinity scale for men, the femininity scale for women, and the masculinity–femininity scale for both sexes.

A relationship between sex role identity and sex role attributes was also evident in an analysis of subjects classified according to sex role type. Table 3 presents the distribution of subjects across the four categories of traditional masculine, traditional feminine, androgynous, and undifferentiated. The percentage of subjects classified into each category corresponded closely to the normative distribution of college men and women reported by Spence and Helmreich (1978). More important, one-way analyses of variance (least squares method) indicated strong sex role identity differences among the groups, $F(3, 100) = 6.59$, $p < .001$ for men and $F(3, 106) = 6.55$, $p < .001$ for women.

Further analysis of sex-typed groups confirmed that sex role identity was related only to masculine attributes for men and only to feminine attributes for women. Men with higher M scores (androgynous and masculine men) reported more masculine sex role identities than men with lower M scores (feminine and undifferentiated men). In contrast, scores on the F scale were irrelevant. Although androgynous men have higher F scores than masculine men, they did not report a significantly more feminine sex role identity. Nor did feminine men report a more feminine identity than undifferentiated men. Similarly, women who scored higher on the F scale (androgynous and feminine women) reported more feminine sex role identities than women who scored lower on the F scale (masculine and undifferentiated women). But women who scored higher on the M scale (androgynous vs. feminine women and masculine vs. undifferentiated women) did not report more masculine sex role identities.

Table 3
Number, Percentage, and Sex Role Identity Means of Men and Women by PAQ Category

PAQ category	Men			Women		
	n	%	*M*	*n*	%	*M*
Androgynous	32	31	24.82[a]	36	33	6.80[a]
Masculine	41	39	26.02[a]	13	11	12.46[b]
Feminine	11	10	22.14[b]	38	34	6.28[a]
Undifferentiated	20	19	21.78[b]	23	21	9.50[b]

Note. Higher mean values indicate a more masculine sex role identity. Within sex, means *not* sharing the same superscript are significantly different at $p < .05$ by weighted contrasts. PAQ = Personal Attributes Questionnaire.

The analyses presented so far can be interpreted as supporting both Kagan's (1964) and Kohlberg's (1966) models of sex role identity, with the exception of subjects' attribute ratings on cross-sex scales, as described above. There are two other correlational analyses, however, on which Kagan's and Kohlberg's theories make distinctly different predictions. First, Kagan's theory predicts a causal link, and therefore a correlation, between sex role stereotypes and sex role identity. Furthermore, these correlations should have the opposite sign of the correlations between attributes and identity (row 4 of Table 2). To illustrate this logic by example: The more masculine *attributes* a man has the more likely he is to compare "favorably" with male stereotypes and infer a highly masculine identity for himself, but the more masculine he perceives the *stereotypic* male to

be, the more likely he is to compare unfavorably and infer a less masculine identity. Kohlberg's theory does not predict any of these correlations because it views sex role stereotypes and sex role identity as two separate, independent variables.

The correlations between sex role stereotypes and sex role identity are presented in the sixth and seventh rows of Table 2. Examining the zero-order correlations first, the predictions derived from Kagan's theory were confirmed in only two of the six comparisons (men on the F scale and women on the M scale). In fact, two of the six correlations were significant ($p < .05$) in the opposite direction from that predicted by Kagan's theory. In case these correlations were contaminated by the influence of sex role attributes, the partial correlations between stereotypes and identity were also calculated. Both of the significantly reversed correlations then disappeared, but no new correlations reached significance in the predicted direction.

Kagan's and Kohlberg's models also lead to opposing predictions about the relationship between sex role attributes and sex role stereotypes. Kohlberg's theory posits a causal link, and therefore a correlation, between sex role stereotypes and sex role attributes. Furthermore, all of these correlations should be positive across the three attribute subscales and for both sexes. The more one sees one's own stereotypic sex as having *any* attribute, the more one should develop that attribute. Kagan's theory predicts no correlations between sex role attributes and sex role stereotypes because it views these as separate, independent variables. The correlations between sex role stereotypes and sex role attributes are presented in the last two rows of Table 2. All six zero-order correlations and five of the six partial correlations reached significance in the direction predicted from Kohlberg's theory.

Discussion

The Nature of Sex Role Identity

This study examined a relatively overlooked concept in current sex role research—sex role identity. A very simple six-item measure of sex role identity was introduced and was shown to have solid internal reliability. Although the instrument contained separate masculine and feminine identity items, thus allowing for multidimensional responses, subjects conceptualized their sex role identity along a single, bipolar dimension. This is not surprising, given that until very recently everyone, including psychologists, viewed masculinity and femininity as diametric. Despite research evidence that masculine and feminine sex role *attributes* form orthogonal dimensions, and despite the increased currency of the term *androgyny*, people are likely to persist in thinking of masculinity and femininity along a single continuum.

This measure of sex role identity was then compared to measures of sex role stereotypes and sex role attributes taken from Spence and Helmreich's (1978) instrument, the PAQ. Two theories of sex role identity were used to derive hypotheses about the relationships among these three sex role variables. Kagan's (1964) theory posits that individuals compare self-perceptions of their own sex role attributes with their perceptions of sex role stereotypes and then infer their relative sex role identity. Kohlberg's (1966) theory posits that people already have firmly established and relatively unchanging sex role identities that guide the development of sex role attributes by means of the modeling or emulating of sex role stereotypes. Both theories predict some shared correlational patterns—namely, that the three sex role variables will form a significant multivariate relationship and, more specifically, that sex role identity and sex role attributes will correlate. On the whole, these predictions were strongly confirmed in the present study, with one exception to be discussed later.

The two theories differ, however, in their predictions about the relationship between sex role stereotypes and the other two variables; Kagan's theory predicts a relationship between stereotypes and identity, whereas Kohlberg's theory predicts a relationship between stereotypes and attributes. Virtually no support was found for the predictions derived from Kagan's theory. Extremely strong support was found for the predictions derived from Kohlberg's theory.

Obviously, the results of a single study may be open to a number of refutations and alternative explanations. Proponents of Kagan's theory could argue, for example, that the instruments used in this study are invalid or measure the wrong sex role attributes and stereotypes and that people base their sex role identities on some other set of traits and stereotypes not tapped by the PAQ. That argument seems implausible, however, for the following reasons. First, there is a wealth of evidence supporting the PAQ as a valid measure (Spence & Helmreich, 1978, 1979). More important, the results of this study demonstrated that sex role identity, attributes, and stereotypes formed a meaningful, coherent, and consistent pattern in nearly every analysis in this study except those analyses derived from Kagan's theory.

Kohlberg's theory of sex role identity was overwhelmingly supported by the present results, with one qualifying detail. It seems that sex role identity influences the development of same-sex-typed attributes (masculine attributes for men and feminine attributes for women) but has little influence on the development of opposite-sex-typed attributes. In retrospect, this makes logical sense. Given that sex role identity is a unidimensional construct, if it were to influence the development of *both* same- and opposite-sex-typed attributes, those attributes would also be unidimensional. Thus, the orthogonality of masculine and feminine attributes and the development of androgynous attributes in some individuals are possible only because the influence of sex role identity is limited to same-sex-typed attributes.

Kohlberg's theory has many important ramifications for future research in the area of sex roles. Conceptually, it suggests that sex role identity may be one of the most powerful and central variables in guiding the development of sex role attributes, in filtering the impact of sex role stereotypes on the individual, and in moderating the influence of situational variables on sex role behavior. Practically, it suggests that sex role identity is a fundamental variable to assess in research on any sex role topic.

The Nature of Sex Role Attributes

Researchers have long debated the meaning of masculinity and femininity or, more precisely, the psychological constructs measured by masculine and feminine attribute scales (Constantinople, 1973; Locksley & Colten, 1979; Pedhazur & Tetenbaum, 1979; Rosenkrantz et al., 1968). Do such scales reflect true masculine and feminine traits (or self-perceptions of traits)? Or do sex role attribute scales merely reflect what respondents think are the socially acceptable, stereotypic attributes for their sex? Spence, Helmreich, and Stapp (1975) argued against the stereotype interpretation of their instrument, the PAQ. They reasoned that the stereotype interpretation would predict a correlation between peoples' perceptions of stereotypes and their PAQ scores. Finding no such correlation in their data, Spence, Helmreich, and Stapp dismissed the stereotype explanation.

The present study included important methodological improvements on Spence, Helmreich, and Stapp's (1975) design and found a significant relationship between sex role stereotypes and sex role attributes. As discussed above, these results support Kohlberg's model of sex role identity. Do these results also present a serious challenge to Spence, Helmreich, and Stapp's trait interpretation of the PAQ? We would argue that these results do not, necessarily, discount the PAQ. In the first place, the absolute size of the correlations between attributes and stereotypes in this study was small. A great deal of variance remained in PAQ attribute scores that could not be accounted for by stereotype scores. Second, a correlation between sex role attributes and stereotypes is not really inconsistent with a trait interpretation of the PAQ. According to Kohlberg's model, stereotypes *should* correlate with attributes precisely because those stereotypes influence the early development of sex role traits. In short, Spence, Helmreich and Stapp's trait interpretation of the PAQ is not damaged by the present results, and their concern about a correlation between the PAQ and sex role stereotypes may be unfounded in light of Kohlberg's theory.

We are cautious, however, about certain

surplus meanings that may accompany the trait view of sex role attributes. At issue is the notion that traits are immutable and intransient aspects of the personality, to be assessed but never changed. An important implication of Kohlberg's theory is that people can and will change, modify, and develop new sex role attributes as their stereotypes change. This notion suggests a line of future research in which subjects' perceptions of stereotypes are manipulated and instruments like the PAQ are used as dependent variables. Such research is not likely to be undertaken, however, if investigators view sex role attributes as fixed and immalleable *personality* traits.

The trait validity of Bem's (1974) sex role attribute scale, the Bem Sex Role Inventory (BSRI), has recently faced more serious challenges than Spence and Helmreich's PAQ. Pedhazur and Tetenbaum (1979) subjected the BSRI to factor analysis and discovered that the two items on the instrument—the items Masculine and Feminine—accounted for nearly 80% of the variance. Furthermore, despite Bem's contention that masculinity and femininity are independent trait dimensions, females who rated themselves high on the Feminine item tended to rate themselves low on the Masculine item, and vice versa for males.

Given the high loadings on the Masculine and Feminine items in the BSRI and the inverse relationship between those items, it seems possible to us that the BSRI actually measures sex role identity rather than sex role attributes. This possibility is given further credence by the results of one of Bem's own studies. Bem and Lenney (1976) gave subjects an opportunity to engage in a variety of sex-typed masculine behaviors (oiling the squeaky lid of a tool box, baiting a fishing hook, etc.) or feminine behaviors (ironing napkins, filling a baby bottle, etc.). They found that masculine and feminine subjects (as determined by BSRI scores) chose sex role appropriate tasks and avoided opposite-sex-typed tasks, even if offered more money to perform the latter. Androgynous subjects, in contrast, freely engaged in whichever sex-typed behavior paid more.

Although Bem and Lenney predicted the above result, it actually provides negative evidence regarding the trait validity of the BSRI. All of the masculine and feminine sex-typed behaviors used in Bem and Lenney's study were in fact highly agentic/instrumental tasks. Baiting a fishhook and ironing a napkin obviously differ in their sex role appropriateness, but they both require agentic manipulation of the physical environment. Thus, in terms of the *traits* that the BSRI supposedly reflects, masculine subjects should have freely engaged in any of the experimental tasks, whereas feminine subjects should have actively avoided all the experimental tasks. If the BSRI measures sex role identity, however, Bem and Lenney's results make perfect sense. Kohlberg's theory postulates that sex role identity guides the individual's modeling of sex role stereotypes. Thus, if the BSRI in fact classifies people by sex role identity, Bem and Lenney's subjects chose exactly the stereotypic tasks one might expect.[3]

The Nature of Sex Role Stereotypes

There has been recent controversy over the apparently tenuous nature of sex role stereotypes (Locksley & Colten, 1979; Pedhazur & Tetenbaum, 1979). Stereotypes of men and women vary markedly as a function of measurement techniques (Ehrlich & Rinehart, 1965) and the inclusion or exclusion of role-specific information about the target (Clifton, McGrath, & Wick, 1976). Some writers have argued that research should focus on sex role schemata rather than on sex role stereotypes (Locksley & Colten, 1979; Spence & Helmreich, 1979). Schemata are more personalistic, situation-specific expectations held by individuals about their own and others' sex role attributes and behaviors, and thus may have more predictive validity than abstract stereotypes.

---

[3] Helmreich, Spence, and Holahan (1979) recently attempted to replicate Bem and Lenney's (1976) results using the PAQ instead of the BSRI. The PAQ failed to predict subjects' choice of sex role behaviors. Ironically, that failure to replicate can be interpreted as positive evidence that the PAQ measures sex role attributes and not sex role identity.

It is interesting to note that Kohlberg frequently used the term *schema* in place of the term *stereotype* in his 1966 theoretical paper. According to him, individuals are exposed to both abstract stereotypes and specific schemata from peers, parents, and other adults. The relevance of sex role information to the individual, or the extent to which the individual models after the stereotypes and schemata provided by others, is guided by his or her sex role identity. From that interaction each individual builds a catalog of very specific personal schemata, intentions, preferences, and behavioral propensities. In short, Kohlberg's theory, with its emphasis on the development of specific, individualistic sex role schemata, presaged many of the current trends in sex role research and could provide an integrative model for future research.

Acknowledgment of Handicap as a Tactic in Social Interaction

Albert H. Hastorf, Jeffrey Wildfogel, and Ted Cassman
Stanford University

Nonhandicapped people often report discomfort and uncertainty when interacting with handicapped individuals. The three studies reported here investigated a possible tactic that handicapped people could use to reduce a fellow interactant's discomfort and uncertainty. Nonhandicapped subjects watched two videotapes of handicapped individuals being interviewed. Each subject then chose the handicapped person with whom he would prefer to work on a cooperative task. Results of all three studies supported the hypothesis that a handicapped person acknowledging his handicap will be preferred to a handicapped person who does not acknowledge his handicap. In Study 1, subjects significantly preferred a handicapped person who acknowledged his handicap to a handicapped person who did not disclose anything personal. In Study 2, subjects significantly preferred an acknowledging person over one who made a personal disclosure other than about his handicap. In Study 3, subjects preferred the individual acknowledging a handicap over one who disclosed something else personal even when the acknowledging individual was clearly nervous about doing so. These results suggest that acknowledging the handicap may be a promising tactic.

Experimental evidence has shown that physical handicaps can negatively affect personal encounters. Nonhandicapped individuals often report discomfort and uncertainty when interacting with handicapped individuals (Davis, 1961; Kleck, Ono, & Hastorf, 1966), and these subjective reports have been corroborated by an objective measure of emotional arousal (Kleck et al., 1966). Further, when interacting with the handicapped, nonhandicapped individuals exhibit less variability in their behavior, express opinions less representative of their actual beliefs, gesture less, and even end the interaction sooner than they do when interacting with a nonhandicapped individual (Kleck, 1968; Kleck et al., 1966). Finally, it has been shown that this tension and discomfort is felt by the handicapped individual on the "other side" of the interaction as well (Comer & Piliavin, 1972).

There are several plausible explanations for the discomforting effect physically handicapped individuals have upon the nonhandicapped. First, nonhandicapped individuals may feel discomfort because the mere presence of a handicapped person forces upon them the realization that they, too, are vulnerable to similar disabilities (Novak & Lerner, 1968). There may also be a fear that the stigma accorded to handicapped individuals is contagious, that being seen with the stigmatized is "discrediting" by association (Goffman, 1963).

Yet another source of the discomforting effect handicapped individuals have on the nonhandicapped may stem from the nonhandicapped individual's uncertainty as to what kind of behavior is expected and appropriate. There are strong societal norms to treat the handicapped kindly and carefully, but there are equally strong norms to treat

This study was partially supported by the Boys Town Center at Stanford University and by National Institutes of Health Grant MH29446-02.

The authors would like to thank William DeJong and Robert Kleck for the helpful comments on an earlier draft of this manuscript. Gregory Northcraft contributed substantially to the final form of the manuscript.

them just like anyone else (Kleck et al., 1966) so as not to appear condescending. Similarly, nonhandicapped individuals may find themselves in conflict over a desire to explore the handicap because it constitutes a novel stimulus and a duty to adhere to strong norms against staring at another person (Langer, Fiske, Taylor, & Chanowitz, 1976). Finally, feelings of discomfort may arise in the presence of a handicapped individual because a deformity is unsightly. Closely related to this is the notion that discomfort arises because the deformity violates our expectations of what a "whole" person should look like (Richardson, 1976).

Whatever the cause of the discomfort felt by nonhandicapped individuals in the presence of the handicapped, it is clear that it makes the physically handicapped the socially handicapped as well. Since the handicapped do not receive accurate feedback concerning the appropriateness of their own behavior or experience the normal behaviors of others, (Hastorf, Northcraft, & Picciotto, 1979) it is likely that their learning of rules about social interactions and their development of sensitivity to others is impaired. In addition, Kleck (1969) has found that although the norms to be kind to the handicapped may result in positive impressions of them in initial encounters, this positive first impression usually attenuates with further interaction. This finding is hardly surprising in view of the impaired social skills development of the handicapped mentioned above. Thus, because of the way the nonhandicapped react to a physical handicap, the handicapped individual may be led to the attribution: "I am the type of person who causes others to feel uncomfortable, and am therefore avoided. When people *do* get to know me, they appear to like me less the better they get to know me." The negative implications for self-concept are not difficult to imagine.

Thus, where the handicapped can be successful in overcoming physical and legal barriers, psychosocial barriers confronting them may prevent their entry into the mainstream of society. The present series of investigations sought to determine if there are tactics the handicapped might employ to overcome these psychosocial barriers.

The discomfort of the nonhandicapped in interactions with the handicapped seems to be a major cause of the psychosocial barriers faced by the handicapped. It therefore seems reasonable that any tactic that reduces this discomfort would facilitate interactions between the handicapped and nonhandicapped. One such tactic may be acknowledging the handicap. Just as one may find it disarming when a relatively short individual introduces himself with the phrase "You may have noticed I'm a little tall for a leprechaun," so might it serve to reduce interactional tension when a handicapped individual conversationally acknowledges his or her handicap. This would seem especially true if the acknowledgment serves the purpose of signaling that the handicap is *not* an interactional obstacle, mention of which or involvement with which must be carefully circumnavigated.

The only study that has investigated the tactic of acknowledging the handicap found that it had no impact on the behavior of nonhandicapped individuals or their ratings of handicapped people (Farina, Sherman, & Allen, 1968). There are, however, circumstances that cast doubts on the validity of this conclusion. The study used male subjects, and its findings are therefore equally consistent with the hypothesis of no relationship between disclosure and liking for nonhandicapped males. Furthermore, the handicapped acknowledgment in the Farina et al. study may not have been effective because it did not reduce the significance of the handicap as a topic of suppressed concern. For acknowledgment of the handicap to be an effective tactic, it may be necessary for the handicapped person to mention it in a manner that conveys that he or she is not overly sensitive about it, that it is all right if the handicap comes up in conversation. The confederate in the Farina et al. study merely mentioned that his handicap caused inconveniences and was the result of a car accident. Such a statement, rather than implying that the handicap is an acceptable topic of conversation, may indicate that the topic has been opened *and closed.*

The present series of investigations explored the tactic of acknowledging the handicap in interaction between handicapped and nonhandicapped individuals. Three studies

were conducted to test the hypothesis that nonhandicapped people would prefer to interact with handicapped individuals who acknowledged their handicap in a manner that showed that they were not overly sensitive about it. In each study, nonhandicapped subjects watched two videotapes, each of a handicapped person in a wheelchair being interviewed. All subjects were told they would interact later with one of the handicapped persons they had viewed. After each interview, subjects gave their impressions of the person they had just seen, and after seeing both interviews, subjects chose the handicapped person with whom they wanted to interact.

Experiment 1

This first study investigated whether nonhandicapped subjects prefer a handicapped confederate who acknowledges his handicap over another who does not. It was hypothesized that nonhandicapped subjects would feel more at ease with the acknowledging confederate and would therefore have more favorable impressions of him and choose to interact with him.

Method

Subjects. Fifty-three male and female students at Stanford University served as subjects. Most were first-year students enrolled in the introductory psychology course. Subjects in the course participated for course credit; others participated for money. Only the data of 48 subjects were included in the analysis. Two subjects declined to state a preference between confederates, 2 subjects suspected that the interviews were staged, and 1 subject had met one of the confederates beforehand. The data of these 5 subjects were omitted from the sample.

Procedure. Subjects were told that the experiment was investigating the effects of seeing and hearing a paraplegic individual (as compared to only reading about him) on future interactions with him. Subjects were informed that the two paraplegics working on the project were extremely busy, and that their schedules were unpredictable. For these reasons, it was explained, they would be shown videotapes of the two paraplegics during this first session and would then return at a later date to perform a simple task with one of them. This cover story provided an opportunity to ask subjects their impressions of the confederates and preferences for a partner without arousing suspicion.

Two interviews of approximately 3½ minutes duration each were taped for four apparent paraplegic confederates. The four tapes of two confederates (Mathew and Peter) were selected for use in the experiment because pretests showed that they were most closely matched on attractiveness and were liked substantially more than the other two confederates. One of the confederates (Mathew) was not actually a paraplegic. His tapes were nevertheless used because pretests confirmed that subjects could not detect which of the four confederates was not a true paraplegic.

The interviews were carefully rehearsed to differ only in whether the interviewee acknowledged his handicap. In all interviews, the confederate told of his happy childhood, good relationship with his parents, part-time work, and plans to take a year off from school. Acknowledgment and nonacknowledgment interviews differed in how the confederate responded to the question, "How do you feel about yourself and your college experience up to this point?" In the acknowledgment interview, the confederate spoke of the problems of being in a wheelchair but said that he had learned to accept the inconveniences. He mentioned that he realized people were afraid to talk about his handicap, but he encouraged them to ask questions, anyway; only in this way could his handicap be gotten out of the way so that people could really get to know him. In the nonacknowledgment interview, the confederate responded that college life was agreeable, that school work kept him rather busy, and that he had recently begun to play clarinet in the school orchestra. Effects of confederate viewed, sex of subject, and order of presentation of the confederates and interview conditions were counterbalanced.

After watching the first interview, subjects rated the handicapped interviewee on an impression scale and answered four questions about him. The impression scale consisted of nine polar adjective pairs separated by a 7-point scale. The adjective pairs were pleasant–unpleasant, positive–negative, excitable–calm, active–passive, strong–weak, tough–fragile, likable–unlikable, well adjusted–poorly adjusted, and hardworking–lazy. Two of the four questions asked how the subject thought the handicapped interviewee would act in certain situations, and two asked how the subject would act in certain situations with the handicapped interviewee. After the second interview, subjects rated the second confederate in the same manner.

Following the second rating, subjects also chose the handicapped person with whom they would prefer to work in the second session. Subjects were told that an effort would be made to give them the partner they chose. Although the experimental situation of choosing between two handicapped people may at first glance seem a strange one, subjects did not seem to consider the situation odd. Now that handicapped people are more in the news, this type of situation is apparently viewed as quite plausible. When the second questionnaire was completed, the experimenter asked each subject to explain the rea-

sons for his or her choice. The experimenter then explained the true purpose of the experiment and answered any questions the subject had.

Results and Discussion

Significantly more subjects (71%) chose to work with the confederate who acknowledged his handicap than with the nonacknowledging confederate, $\chi^2(1) = 7.52$, $p < .01$. Analyses of the effects of confederate viewed, sex of subject, and order of presentation of the confederates and interview conditions did not reveal any significant differences in which confederate was preferred. Furthermore, 79% of the subjects who chose the acknowledging confederate reported that the acknowledgment was an important factor in their decision. Clearly the acknowledgment exerted a major influence on working partner preference.[1]

Sign tests revealed that of the four questions asked each subject about the confederates, only the question "Do you think you would feel uncomfortable during a conversation with the interviewee and your friends, if someone began talking about a touch football game?" successfully distinguished between acknowledging and nonacknowledging confederates, $p < .05$. This suggests that subjects chose to work with the acknowledging confederate because they anticipated feeling more comfortable in his presence.

Analysis of the polar adjectives revealed that the acknowledging confederate was rated more favorably on the evaluative and potency factors and was perceived as more likable and better adjusted, smallest $t(47) = 2.02$, $p < .05$. Subject ratings of the handicapped confederates thus also support the hypothesis that acknowledging the handicap is an effective tactic for increasing working-partner preference. Moreover, the subjects' ratings suggest that the acknowledging tactic may be successful because it introduces the handicapped person as someone who is not overly sensitive about his handicap.

Experiment 2

The results of Experiment 1 suggest that acknowledging the handicap is an effective tactic in handicapped/nonhandicapped interaction because acknowledgment reduces discomfort of the nonhandicapped interactant. However, the findings of the first study do not rule out the possibility that the effectiveness of acknowledgment arises because the acknowledgment reveals personal information, thereby increasing intimacy and liking (Jourard, 1959; Worthy, Gary, & Kahn, 1969). A second study therefore compared the preferences of nonhandicapped subjects who had watched a handicapped confederate who acknowledged his handicap and another who disclosed something else personal but did not mention his handicap. Since it was hypothesized that it is acknowledgment of the handicap that helps nonhandicapped individuals feel less uncomfortable and influences their preferences, it was expected that subjects would still have more favorable impressions of, and choose to interact with, the confederate who acknowledged his handicap.

Method

Subjects. Fifty-five male and female students from the same subject population as in Experiment 1 participated in the second study. The data of 48 subjects were included in the analysis. Three subjects were suspicious that the interviews were staged, and 4 subjects had met or heard about one of the confederates. The data of these 7 subjects were omitted from the analysis.

Procedure. The procedure was identical to that of Experiment 1, except that the two interviews that subjects watched featured a confederate who acknowledged his handicap and one who made a personal disclosure unrelated to his handicap. This personal disclosure interview replaced the nonacknowledgment interview of the first experiment.

In the personal disclosure interview, the confederate stated that school was going well and that he had several good friends but that recently he and his girlfriend of 8 months had been having problems. He then described their uncertainty about next year and the "weird religious trip" his girlfriend's mother was "laying on her." He finished the interview by saying that he hoped it all worked out. Although there are other types of disclosures that might have

[1] A similar finding has since been reported. An unpublished paper by Bazakas (Bazakas, Note 1) reports that acknowledgment of the handicap results in more favorable reactions toward a handicapped confederate only when he presents himself as a "coping" person.

been used, this type of disclosure had the advantage of being very revealing. Whether other types of disclosures might have different effects on preferences for the handicapped is a question that merits further exploration.

The dependent measures were essentially the same as those used in Experiment 1. One of the adjective pairs for the activity factor (excitable–calm) was replaced by fast–slow, and three more polar adjective pairs were added (warm–cold, considerate–inconsiderate, and friendly–unfriendly). *Fast–slow* replaced *excitable–calm* because the two adjective pairs comprising the activity factor were insignificantly correlated in the first experiment ($r = .04$).

Results and Discussion

As predicted, subjects preferred the confederate who acknowledged his handicap over the one who made a personal disclosure unrelated to his handicap, $\chi^2(1) = 13.02$, $p < .001$. Fully 77% of subjects chose to work with the confederate acknowledging a handicap.

As in Experiment 1 there were no preference effects due to confederate viewed, sex of subject, or order of presentation of the confederates and interview conditions.

As a manipulation check of personal disclosure, the personal disclosure interviews from Experiment 2 and the nondisclosure interviews from Experiment 1 were shown to 32 additional subjects who rated the interviews on 17 polar adjective pairs. Two of these adjective pairs were combined into a "disclosing" measure. The scales were open–closed and secretive–revealing. A t test of these ratings revealed that there was a tendency to see the personal disclosure confederate as more disclosing, $t(31) = 1.67$, $p < .11$. Although the personal disclosure interview may have differed from the nondisclosure interview on other dimensions, this notion cannot be properly tested. There is no way to distinguish whether other differences would be due to the disclosure itself or to the specific type of disclosure used.

As in Experiment 1, belief in the importance of the handicap acknowledgment in determining subjects' preferences for partner is substantiated by the reports of subjects who chose to work with the confederate who acknowledged his handicap. Eighty-two percent of the subjects choosing the acknowledging confederate stated that handicap acknowledgment was an important factor in the decision.

A sign test on the question "Would you be more comfortable" found that subjects thought they would be significantly more comfortable with the acknowledging confederate, $p < .05$. Again, this suggests that choice of partner may be related to how comfortable acknowledgment of the handicap makes the nonhandicapped individual feel. Analyses of the polar adjectives revealed that the confederate acknowledging the handicap was rated more favorably on the evaluative factor and was perceived as both better adjusted and more friendly, smallest $t(47) = 2.19$, $p < .05$.

The results of Experiment 2 again support the hypothesis that acknowledgment of the handicap (and not just the volunteering of something personal) is an effective tactic in increasing partner preference. Further, the findings of this second study are consistent with the hypothesis that the acknowledgment tactic is effective because it helps the handicapped individual appear less sensitive about his handicap, thereby making those who interact with him more comfortable.

Experiment 3

It may be difficult, at least for some handicapped individuals, to encourage the nonhandicapped to ask questions about their handicap. Handicapped individuals are, in fact, often sensitive about their handicaps and will probably not be able to use the tactic of acknowleging their handicap without showing nervousness and apprehension. Before recommending a tactic, it is important to know something of its limits. This third study explored the consequences for a handicapped individual of showing signs of tension and anxiety while acknowledging the handicap.

It was hypothesized that nonverbally communicated nervousness would cast a different interpretation upon the confederate's acknowledgment of the handicap. Specifically, it was hypothesized that this nervousness would lead the subject to feel that it was *not* acceptable to talk about the handicap. The

characteristic response to discrepant information is to rely more on the nonverbal than the verbal information (Mehrabian, 1971). Consequently, subjects might feel even more uncomfortable around a handicapped person who (nonverbally) showed discomfort about being handicapped while verbally insisting otherwise. It was therefore predicted that the findings of the first two experiments would be reversed: that subjects would have more favorable impressions of, and choose to interact with, a confederate who disclosed something personal but neither mentioned the handicap nor showed signs of nervousness while being personal.

Method

Subjects. Fifty-two male and female students from the same subject population as in Experiments 1 and 2 participated in the study. The data of 48 subjects were included in the analysis. Three subjects had met or heard about one of the confederates, and 1 subject declined to state a preference between confederates. The data from these 4 subjects were omitted from the sample.

Procedure. The procedure was virtually identical to that of Experiment 2, except that a "nervous" acknowledgment of handicap replaced the interview acknowledging the handicap of the second experiment. The verbal text of the interviews remained unchanged. However, during most of the handicap acknowledgment in the nervous condition, the confederate attempted to display tension by avoiding eye contact, running his hand through his hair, and clasping his hands tightly together. The other interview, as in Experiment 2, was of a confederate who made a personal disclosure. In this interview, the confederate neither mentioned his handicap nor showed signs of nervousness. The dependent measures were the same as in Experiment 2.

Results and Discussion

Contrary to predictions, subjects tended to prefer the confederate who acknowledged his handicap, $\chi^2(1) = 3.52$, $p < .07$, even when he was nervous about doing so. Sixty-five percent of subjects chose to work with this confederate.

An analysis of the effects of confederate viewed, sex of subject, and order of presentation of the confederates and interview conditions revealed that the order of presentation of the interview condition significantly affected confederate preferences, $\chi^2(1) = 5.83$, $p < .02$. That is, the confederate who was nervous while acknowledging his handicap was preferred significantly more often when he was seen first than when he was seen second. Since order of presentation of the interview condition did not affect confederate preferences in the first two studies, this finding is difficult to explain. Nevertheless, it remains striking that although the confederate who acknowledged his handicap was clearly nervous about doing so, he was still preferred.

As a manipulation check on perceived nervousness, the nervous acknowledment of handicap and personal disclosure interviews were shown to 32 additional subjects who rated each interviewee on 17 polar adjectives. Three of the adjective pairs were combined into a "nervousness" measure. The scales were at ease–nervous, relaxed–tense, and comfortable–uncomfortable. A t test of these ratings revealed that the nervous handicap acknowledgment interview was seen as significantly more nervous than the personal disclosure interview, $t(31) = 2.32$, $p < .05$. There were no differences in perceived nervousness of the confederate who acknowledged a handicap as a function of whether he was seen first or second.

Even though the confederate was perceived as nervous while acknowledging his handicap, 74% of subjects choosing the acknowledging confederate identified the acknowledgment of handicap as an important factor in their decision, and 19% of subjects who chose the nervous confederate did so despite acknowledging that the confederate clearly was not comfortable with his own handicap. Apparently, then, some subjects may have chosen the nervous confederate because he was *trying* to cope with his handicap.

Subjects realized that they would be just as uncomfortable around the confederate who acknowledged a handicap as around the confederate who only made a personal disclosure; more than half of the subjects reported that they would be uncomfortable around the confederate who acknowledged his handicap. Finally, nervousness while acknowledging did have a negative effect, as 76% of subjects who rejected the nervous, acknowledging confederate stated that they

rejected him because he did not seem adjusted to his handicap.

The nervous confederate was perceived to be more passive, $t(47) = 2.12$, $p < .05$. Comparison of no other polar adjective pair ratings attained significance. However, the variance of the ratings on 10 of the 12 adjective pairs was larger when subjects were rating the nervous, acknowledging confederate. A check on the variance of subject ratings in the first two experiments revealed that this pattern of variance in the third experiment was a significant reversal of the pattern in the first two studies, $\chi^2(2) = 38.6$, $p < .001$. One interpretation of these results is that in the first two experiments, subjects were more certain how to act with the confederate acknowledging a handicap because his communication in acknowledging made it clear what behavior was appropriate. Impressions of subjects were therefore relatively uniform. In contrast, the message of the acknowledgment of handicap in the third experiment was ambiguous. While verbally communicating an openness about his handicap, the nervous confederate was clearly betraying an anxiousness about the topic nonverbally. As a result, impressions of subjects were uncertain and thereby varied.

This interpretation is consistent with the ambivalence hypothesis suggested by Katz and his colleagues (Katz, Glass, & Cohen, 1973; Katz, Glass, Lucido, & Farber, 1977). They point out that ambivalence creates a tendency toward behavioral instability. As a result, any positive information amplifies favorable attitudes, and similarly, any negative information amplifies unfavorable attitudes. Our subjects, like most nonhandicapped individuals, probably have ambivalent (approach/avoidance conflicted) attitudes toward the handicapped. Acknowledgment of the handicap in the first two experiments was positive information because it reduced discomfort. Therefore, it amplified favorable impressions of the acknowledging confederates. Acknowledgment of the handicap in the third experiment contained both positive information (verbally) and negative information (nonverbally). Therefore, it amplified either favorable or unfavorable impressions, depending on which source of communication was more salient for each subject. This possibility of amplification of impressions in either direction accounts for the increased variance found in ratings of the acknowledging confederate in Experiment 3; the probable high salience of his nervousness accounts for the reduced effectiveness of the acknowledging tactic.

General Discussion

The findings of these three experiments have important implications for social policy; the tactic of acknowledging a handicap seems very promising. In all three studies, the confederate who acknowledged his handicap was preferred to the other handicapped confederate. This finding was true even if the other confederate made a personal disclosure.

In contrast to the results of investigations on personal disclosure (Ehrlich & Graeven, 1971; Jourard & Landsman, 1960), acknowledgment of the handicap was effective even though males were doing the acknowledging. Perhaps the macho stereotype of males, which views *disclosure* as weak and effeminate, is not a barrier to the acknowledging tactic.

It is noteworthy that the acknowledging confederate was still slightly more preferred even when he was clearly nervous about the acknowledgment. This suggests that handicapped people may use the tactic effectively even before they are well adjusted to their handicap. By acknowledging their handicap, handicapped individuals can reduce the discomfort and uncertainty of the nonhandicapped and thereby increase their opportunities for social interaction and its accompanying benefits. This increased opportunity for social interaction can then itself help promote smoother adjustment to the handicap.

Further research is needed, however, to explore the impact of the acknowledgment tactic. It would be useful to know, for instance, if the acknowledgment tactic attenuates the biased, inhibited behavior that the nonhandicapped usually demonstrate in the presence of handicapped individuals. The behavior of nonhandicapped individuals should be measured in interactions with handicapped individuals employing the acknowl-

edgment tactic. Studies of this kind will ultimately determine the utility of acknowledging the handicap.

Characterological Versus Behavioral Self-Blame: Inquiries Into Depression and Rape

Ronnie Janoff-Bulman
University of Massachusetts—Amherst

Two types of self-blame—behavioral and characterological—are distinguished. Behavioral self-blame is control related, involves attributions to a modifiable source (one's behavior), and is associated with a belief in the future avoidability of a negative outcome. Characterological self-blame is esteem related, involves attributions to a relatively nonmodifiable source (one's character), and is associated with a belief in personal deservingness for past negative outcomes. Two studies are reported that bear on this self-blame distinction. In the first study, it was found that depressed female college students engaged in more characterological self-blame than nondepressed female college students, whereas behavioral self-blame did not differ between the two groups; the depressed population was also characterized by greater attributions to chance and decreased beliefs in personal control. Characterological self-blame is proposed as a possible solution to the "paradox in depression." In a second study, rape crisis centers were surveyed. Behavioral self-blame, and not characterological self-blame, emerged as the most common response of rape victims to their victimization, suggesting the victim's desire to maintain a belief in control, particularly the belief in the future avoidability of rape. Implications of this self-blame distinction and potential directions for future research are discussed.

In a study by Bulman and Wortman (1977) on the relationship between blame attributions and coping, self-blame emerged as a predictor of good coping among paralyzed victims of freak accidents. A conclusion that is consistent with these results—that self-blame is a positive psychological mechanism—derives primarily from the implications of this attribution for a belief in personal control over one's outcomes. The advantages of perceived control have been repeatedly demonstrated in social psychological experiments (see, e.g., Bowers, 1968; Glass & Singer, 1972; Langer & Rodin, 1976; Schulz, 1976); Walster's (1966) formulation of observers' reactions to victims and Kelley's (1971) view of attributional processes "as a means of encouraging and maintaining [his] effective exercise of control in the world" (p. 22) are also based upon a recognition of the significance of perceived control. The tenuous link between control and self-blame becomes comprehensible as one realizes that in order to maximize a belief in control when attributing blame to particular factors, one's choice is influenced by the perceived modifiability of the potential factor(s). As Medea and Thompson (1974) write in the case of rape, "If the woman can believe that somehow she got herself into the situation, if she can make herself responsible for it, then she's established some sort of control over rape. It wasn't someone arbitrarily smashing into her life and wreaking havoc" (p. 105).

Unfortunately, this adaptive, control-oriented view of self-blame too easily ignores the more popular conception of the phenomenon, by which self-blame is regarded as maladaptive, a correlate of depression, and a reflection of psychological problems. Thus Beck (1967), writing about depressed pa-

The author thanks Philip Brickman, Irene Frieze, and Camille Wortman for their valuable comments on an earlier draft of this article.

tients, states, "Another symptom, self-blame, expresses the patient's notion of causality. He is prone to hold himself responsible for any difficulties or problems that he encounters" (p. 21). Self-blame as a maladaptive psychological mechanism is generally related to harsh self-criticism and low evaluations of one's worth.

Two Types of Self-Blame

Recognizing that self-blame may be both adaptive and maladaptive is a first step towards the conclusion that there are two different types of self-blame, one representing an adaptive, control-oriented response, the other a maladaptive, self-deprecating response. The primary distinction between these two self-attributions is the nature of the focus of blame, for it is proposed that the control related self-blame focuses on one's own behavior, whereas the esteem related self-blame focuses on one's character, an overall view of the kind of people individuals perceive themselves to be. In other words, individuals can blame themselves for having engaged in (or having failed to engage in) a particular activity, thereby attributing blame to past behaviors; or individuals can blame themselves for the kind of people they are, thereby faulting their character. To facilitate discussion of these two self-attributional strategies, the esteem related blame will be labeled "characterological" self-blame and the control related type, "behavioral" self-blame. In the case of rape, for example, a woman can blame herself for having walked down a street alone at night or for having let a particular man into her apartment (behavioral blame), or she can blame herself for being "too trusting and unable to say no" or a "careless person who is unable to stay out of trouble." This behavioral–characterological distinction parallels findings in the area of the just world theory. In their recent review, Lerner and Miller (1978) state that innocent victims who cannot be characterologically blamed (i.e., derogated) by virtue of their reputedly good character are instead blamed for some behavior in which they engaged (i.e., behavioral blame).

While this distinction between characterological and behavioral self-blame appears related to the state–trait distinction in clinical psychology (see, e.g., Spielberger, 1972), it more specifically corresponds to the distinctions drawn by Weiner and his colleagues (Weiner et al., 1971) in their scheme of attributions in the area of achievement. In attributing failure to oneself (internal attribution), one can point to his/her own lack of ability or effort, attributions that have very different implications for perceived control. Individuals who make an attribution to poor ability believe that there is little they can do to control the situation and succeed, for ability is stable and relatively unchangeable. Effort attributions, on the other hand, will lead one to believe that as long as he/she tries harder, he/she will be able to control outcomes in a positive manner (see Dweck, 1975). Similarly, characterological self-blame corresponds to an ability attribution, and behavioral self-blame corresponds to an effort attribution, having very different implications for perceived personal control. While the dimension used by Weiner and his colleagues to distinguish between ability and effort is that of stability (stable–unstable), the differences between the attributions may also be captured through the use of a controllability dimension (cf. Elig & Frieze, 1975; Weiner, 1974). The primary distinction to be drawn between behavioral and characterological self-blame is the perceived controllability (i.e., modifiability through one's own efforts) of the factor(s) blamed.

In a recent reformulation of learned helplessness, Abramson, Seligman, and Teasdale (1978) have posited a third dimension of attributions—global–specific—that is important to specify in determining subsequent perceived helplessness. While this global–specific dimension characterizes one of the differences to be noted between characterological and behavioral self-blame, it is proposed that the dimension of significance distinguishing these two types of self-blame is perceived controllability, and the global–specific and stable–unstable dimensions are important because of their contribution to perceived control. Abramson, Seligman, and Teasdale (1978), however, note that the dimension of "controllability is logically orthogonal to the

Internal × Global × Stable dimensions . . ." (p. 62). The position presented here is consistent with a comment by Wortman and Dintzer (1978) in their recent reaction to the learned helplessness reformulation. They state, "We feel that assessments of the controllability of the causal factor may be of the utmost importance in predicting the nature and magnitude of subsequent deficits" (p. 82).

In a discussion of self-blame by Abramson, Seligman, and Teasdale (1978) these authors state that self-blame in helplessness and depression follows from the "attribution of failure to factors that are controllable" (p. 62). The self-blame they are dealing with is that which is consistent with "self-esteem deficits" and "self-criticism" and thus parallels characterological self-blame. The authors do not recognize a second type of self-blame, behavioral self-blame, which according to the present analysis is the type of self-blame following from attributions to controllable factors. Contrary to the assertions of Abramson, Seligman, and Teasdale, it is proposed that characterological self-blame follows from attributions to uncontrollable factors.

A further distinction between behavioral and characterological self-blame lies in the time orientation of the attributor. It is proposed that in blaming one's behavior, an individual is concerned with the future, particularly the future avoidability of the negative outcome. This concern for future avoidability is consistent with the control-motivated basis for behavioral self-blame. The future-oriented concerns of behavioral self-blamers need not focus exclusively on the future avoidability of the negative outcome for which the attributor is blaming him/herself; rather, behavioral self-blame may promote a general belief in one's ability to avoid negative outcomes and to effect positive outcomes in the future. Thus, the paralyzed victims in the Bulman and Wortman (1977) study were apt to be better copers if they blamed themselves, but self-blame was more likely to be in the service of a general belief in future control (e.g., I'll be able to improve my physical condition through physical therapy), rather than a more specific belief in the future avoidability of their own paralysis, which was medically regarded as irreversible in all cases.

In blaming himself or herself characterologically, the individual is not concerned with control in the future, but rather with the past, particularly deservingness for past outcomes. Individuals who engage in behavioral self-blame are apt to have an eye towards the future and what they can do to avoid a recurrence of the negative outcome (or the occurrence of negative outcomes in general). Individuals who engage in characterological self-blame are apt to focus more on the past and what it was about them that rendered them deserving of the negative outcome for which they are blaming themselves.[1] Perceived avoidability and behavioral self-blame are thus assumed to be part of the same blame cluster, whereas characterological self-blame and feelings of deservingness are representative of another blame cluster.

Self-Blame and Depression: Toward the Resolution of a Paradox

Distinguishing between characterological and behavioral self-blame may be a first step toward resolving the "paradox in depression" recently recognized and discussed by Abramson and Sackeim (1977). According to these authors, there are two symptom clusters of depression, one represented by hopelessness, powerlessness, and futility, the other by self-blame, self-deprecation, and guilt. Abramson and Sackeim discuss two prominent theories of depression that are based on cognitions of hopelessness and self-blame. Seligman's (1975) theory of learned helplessness suggests that depression results from a belief in the uncontrollability of outcomes. According to Beck's (1967) theory of depression, the depressed individual blames him/herself for negative outcomes, particularly personal failures. It is the conjunction of these two models that accounts for the paradox. That

[1] These distinctions are consistent with a recent analysis of responsibility by Harvey and Rule (1978), in which causal responsibility and deservingness are regarded as conceptually distinct aspects of responsibility.

is, how can individuals blame themselves for outcomes over which they feel they have had no control? How can an individual feel both helpless and self-blaming? Abramson and Sackeim discuss several possible resolutions to this paradox but remain dissatisfied with the alternatives presented to date. However, a recognition of self-blame, not as a unitary phenomenon, but rather as a label for two very different self-attributional strategies, may inform and resolve the apparent paradox in depression.

One reason why a resolution to the depression paradox has not been forthcoming is suggested by Abramson, Seligman, and Teasdale's (1978) assertion (presented above) that self-blame follows from attributions to controllable factors. In assuming that self-blame naturally involves blaming controllable factors, the possibility that individuals can simultaenously feel they do not have control and blame themselves is foreclosed. Instead, if we recognize the distinction between behavioral and characterological self-blame, then the paradox begins to disappear. Essential to an understanding of this assertion is the proposition that in blaming himself or herself for the kind of person he/she is, the individual is not necessarily placing blame for an event regarded as personally controllable. A person can believe that he/she deserves what happened and is therefore "responsible" for it (see Harvey & Rule, 1978), without believing that he/she is capable of altering the outcome in the past, present, or future.

In the case of personal failures, the characterological blamers will point to deficits in themselves that are believed to account for these failures. The deficits are likely to lie in the realm of characteristics that generally define them, characteristics that are relatively nonmodifiable, stable, and global. Thus, in achievement tasks, an ability attribution would represent a characterological self-blaming strategy. In the case of self-blame for failures that are further removed from the individual, represented by the "delusions of depressives" who blame themselves for the "violence and suffering in the world" (see Beck, 1967), the individuals appear to regard themselves as being punished for who or what they are. In this case, rather than perceive themselves as responding, active organisms, depressed individuals seem to perceive themselves as passive stimuli. They do not believe they actively bring about outcomes that remain under their control. Rather, negative outcomes occur in reaction to them by other people and the world at large. In sum, self-blame by depressives is proposed as characterological in nature. Since characterological self-blame and feelings of helplessness are not logically inconsistent, their conjunction in depressed individuals should not be regarded as paradoxical.

Self-Blame Among Rape Victims

The association between self-blame and depression is probably well recognized and accepted within this culture. While the association between self-blame and rape is probably not as strong, the more or less popular image of the self-blaming rape victim may be more accurate than many would like to believe. The pervasiveness of self-blame has been well documented in literature on rape (see, e.g., Burgess & Holmstrom, 1974a, 1974b, 1976; Griffin, 1971; Hursch, 1977; Weis & Weis, 1975; Bryant & Cirel, Note 1). Although fear (of injury, death, and the rapist) is the primary reaction to rape, self-blame may be second only to fear in frequency of occurrence; perhaps surprisingly, it is far more common than anger.

In considering the few existing facts on victim precipitation in the crime of rape, however, it becomes obvious that the victims' self-attributional strategies (i.e., self-blame) do not reflect an accurate appraisal of the woman's causal role in the assault. The National Commission on the Causes and Prevention of Violence (1969) concluded that only 4.4% of all rapes are precipitated by the victim. Although a higher figure, 19%, has been proposed by Amir (1971), he used a considerably broader definition in establishing his criteria for victim precipitation. Thus, criteria such as "risky situations marred with sexualty" were used, affording the interpreter of data considerable discretion. In light of these percentages, the pervasiveness of self-blame becomes a puzzling phenomenon.

An attempt to account for the pervasiveness of such feelings has involved the proposition that women have been socialized to accept blame for their own victimization. As Brownmiller (1975) suggests, women are conditioned to a female victim mentality. Brownmiller discusses the psychologies of Deutsch and Horney and concludes that masochism is a female trait, one that has been socialized by men. Similarly, Burgess and Holmstrom (1974a) contend that women are socialized to the attitude of "blaming the victim," a perspective shared by Bryant and Cirel (Note 1). While there is no doubt much truth to this socialization hypothesis, it may paint a very incomplete picture of the factor(s) responsible for self-blame in women and the rape victim in particular. It fits nicely with a portrait of women as helpless and masochistic and may unwittingly perpetuate a view of women too consistent with the role of rape victim. In particular, this view entirely overlooks the possibility that self-blame by victims of rape may represent an adaptive response, an attempt to reestablish control following the trauma of rape.

A common reaction to rape is the feeling of a loss of control over one's life (Bard & Ellison, 1974; Bryant & Cirel, Note 1). The woman does not feel sure of herself and questions her self-determination. She needs to feel a sense of control (Hilberman, 1976), for she feels extremely vulnerable and particularly fears the rapist and a recurrence of rape. In blaming herself, perhaps the rape victim is engaging in a type of self-blame that maximizes a belief in control; that is, perhaps rape victims engage in behavioral self-blame rather than characterological self-blame. Whereas the latter type of blame would provide some support for a view of women as helpless and masochistic, the former would foster a different image of the rape victim and her reactions, that of an individual reacting in an adaptive manner to her recent loss of control.

If the rape victim engages in behavioral self-blame and attributes her victimization to a modifiable behavior (e.g., I should not have walked alone, I should have locked the windows), she is likely to maintain a belief in the future avoidability of a similar misfortune, while simultaneously maintaining a belief in personal control over important life outcomes. If, on the other hand, the rape victim blames herself characterologically, attributing the victimization to more or less unchangeable factors (e.g., I'm a weak person and can't say so, I'm the type of person who attracts rapists), she will presumably be considerably less likely to believe that she is capable of alleviating her vulnerability in the future and may begin to perceive herself as a chronic victim.

Two studies were conducted in order to test the usefulness of the distinction between behavioral and characterological self-blame in the areas of depression and rape. Study 1 was designed to determine whether characterological self-blame is a distinguishing characteristic of depressed individuals and whether it co-occurs with decreased beliefs in personal control among female college students. Study 2 involved surveying rape crisis centers across the country in order to determine which type of self-blame—behavioral or characterological—more accurately characterizes the reactions of rape victims served by these centers.

Study 1: Depression

Method

Subjects. Subjects were 129 undergraduate women at a large state university who were volunteers drawn from a number of undergraduate psychology courses. Each received one experimental credit for her participation. Responses from 9 of the subjects lacked much data, and these were eliminated from the analyses, leaving the responses of 120 subjects.

Procedure. Data [2] were collected during group sessions that generally ranged from 10 to 15 students. Subjects were told that we were interested in the relationship between personality variables and artistic taste, and that there would be three parts

[2] These data were collected by Laurie Gunsolley for her senior honors thesis, which was designed and completed under the direction of the author. While Gunsolley was particularly interested in self-esteem, the data have been reanalyzed for this presentation, using the responses to the Zung Self-Rating Depression Scale (1965) as the basis for distinguishing between the two groups of interest.

to the study: completing personality scales, viewing and rating a series of art slides, and reacting to several "real-life" types of situations. The subjects were asked to complete three personality scales. The Zung Self-Rating Depression Scale (Zung, 1965) was used to measure depression.[3] In addition, subjects completed the Janis–Field Feelings of Inadequacy Scale (Eagly, 1967), a self-esteem measure, and the Rotter Internal–External Locus of Control Scale (Rotter, 1966). Having completed these, the subjects were then asked to rate seven art slides on "aesthetic appeal." An overhead projector was used to show the slides, and ratings were made on 5-point scales. These artistic ratings not only provided a "cover" for the study but, more important, served as a distraction between the first (personality scales) and third (self-blame measures) parts of the experiment.

In the third phase of the study, subjects were asked to read four scenarios and to imagine that the various situations described had actually been experienced by them; that is, they were told to react to the scenarios given that they were the target people presented. In each situation the outcome was negative and the role of the target person was intentionally ambiguous. The scenarios involved the following situations: (a) a car driven by the target person is in an accident on a snowy winter day; (b) a social invitation by the target person is rejected (on the basis of false excuses) by an individual she recently met and regarded as a friend: (c) an urgent call for a roommate results in the target person's taking down the wrong number; the roommate is subsequently unable to return the call successfully; (d) an intense love relationship is ended when the target person's boyfriend leaves her and immediately gets involved with another woman.

Subjects were asked to respond to five questions following each scenario; responses were made on 6-point scales with endpoints *not at all* and *completely*. Subjects were asked to indicate how much they blamed themselves, other people, the environment (i.e., impersonal world), and chance, for the situations described. The question that tapped characterological self-blame asked, "Given what happened, how much do you blame yourself for the kind of person you are (e.g., the kind of person who is in an accident [Scenario A], the kind of person who has invitations turned down [Scenario B], the kind of person who causes inconveniences for others [Scenario C], the kind of person who is rejected in relationships [Scenario D])?" The appropriate "kind of person" was included separately for each scenario, so that for scenario D only "the kind of person who is rejected in relationships" was included. Question 3 sought to tap behavioral self-blame and asked, "Given what happened, how much do you blame yourself for what you did (e.g., your driving behavior [Scenario A], how you acted when you first met the person [Scenario B], how you acted when taking down the telephone number [Scenario C], how you acted with your boyfriend [Scenario D])?" Question 4 asked, "How much do you think you deserved what happened?" and Question 5 following each scenario was, "If the same situation arose in the future, to what extent do you believe that you could avoid what happened in this case?" All subjects were thoroughly debriefed upon completion of the session.

Results

Using a median split, subjects were divided into nondepressed (responses ranged from 6 to 21 on the Zung scale) and depressed (22 to 45 on the Zung scale) groups.[4] On the Janis–Field Feelings of Inadequacy Scale, the depressed group scored lower (i.e., had lower self-esteem) than the nondepressed group (64.05 vs. 74.97), $F(1, 118) = 36.72$, $p < .001$, and the depressed group was found to be more external than the nondepressed group on Rotter's Internal–External Locus of Control Scale (13.36 vs. 10.57), $F(1, 118) = 12.32$, $p < .001$.

Parallel attributional and self-blame measures were summed across the four scenarios; for example, a score for characterological blame was derived by adding the individual responses to each of the four questions (one following each scenario) that asked about characterological self-blame. In order to justify adding the four scales, alpha reliability coefficients were calculated for each of the eight summed scores. Despite the fact that each was composed of four scores, only the perceived avoidability measure failed to reach a reliability of .50. The general self and other people attributions were less than .60, and the other five measures had alpha reliabilities between .62 and .74.[5] Each

---

[3] In accordance with work on depression by Bonnie Strickland, a clinical psychologist in the Department of Psychology, University of Massachusetts, Amherst, a response category labeled "none of the time" was added to the Zung Self-Rating Depression Scale (1965). According to Strickland (personal communication), this renders the scale particularly sensitive to depression in a college population.

[4] Male and female college students completed the same depression scale in a study by Haley and Strickland (Note 2); their data had a median of 23.

[5] Nunnally (1967) writes that in early work on "hypothesized measures of a construct", reliabilities of .50 or .60 are sufficient standards (see p. 226).

summed score could range from a total of 0 to 24.

The depressed and nondepressed groups did not differ in the amount of blame they attributed to themselves in general, nor did they differ in the amount of behavioral self-blame reported, $F(1, 118) = 2.47$, *ns*. However, the groups did differ significantly in the amount of characterological self-blame reported, with more characterological self-blame reported by the depressed than the nondepressed group (11.59 vs. 10.03), $F(1, 118) = 4.33$, $p < .05$. Other differences on the total scores were found for attributions to chance; consistent with their greater externality on Rotter's scale, the depressed group blamed chance more than the nondepressed group (11.38 vs. 9.73), $F(1, 118) = 4.54$, $p < .05$. Further, there was a marginally significant difference between the two groups on the question of how much they felt they deserved what happened, with the depressed group reporting greater deservingness than the nondepressed group (8.31 vs. 7.24), $F(1, 118) = 3.68$, $p = .057$.[6]

A stepwise discriminant analysis was conducted in order to determine the variables that differentiated best between the two groups. All blame attribution measures were entered, with the exception of general self-blame, since characterological and behavioral self-blame were assumed to be finer distinctions of the general measure. Attributions to chance emerged as the best discriminator, $F(5, 114) = 4.54$, Wilks $\lambda = .963$, and characterological self-blame emerged as the next strongest differentiator, $F(5, 114) = 3.29$, Wilks $\lambda = .937$. These were followed, respectively, by attributions to other people, environment, and behavioral self-blame.

The correlations between deservingness, perceived avoidability, and the two types of self-blame were all strong. As an exploratory tool, an analysis of variance was conducted in order to further investigate the relationship between the variables. It should be noted that the low reliability of the avoidability measure calls for caution in interpreting the results of this analysis. Median splits were performed on the behavioral self-blame and characterological self-blame totals, and deservingness and avoidability totals were each analyzed by behavioral (high–low) and characterological (high–low) self-blame. A main effect for characterological self-blame emerged from the analysis of deservingness, with less deservingness reported by those who engaged in low characterological self-blame as compared with those who engaged in high characterological self-blame (6.20 vs. 9.26), $F(1, 119) = 29.78$, $p < .001$. On the other hand, a main effect for behavioral self-blame emerged from the analysis of perceived future avoidability, with less perceived future avoidability reported by those who engaged in low behavioral self-blame as compared with those who engaged in high behavioral self-blame (11.89 vs. 13.88), $F(1, 118) = 6.85$, $p < .01$.

Discussion

When self-blame was treated as a single entity (i.e., "self" as one of several possible factors tapped for blame attributions), no differences were found between the depressed and nondepressed students on this variable. However, when self-blame was divided into two types of self-attributions, behavioral and characterological, differences between the groups emerged. While the depressed and nondepressed students did not differ in terms of behavioral self-blame, they did differ significantly in terms of characterological self-blame; that is, the depressed students blamed themselves more characterologically than did the nondepressed students.

The suggestion that characterological self-blame follows from attributions to uncontrollable factors received strong support. Those who were depressed were more likely to attribute negative outcomes to chance, a variable that differentiated best between the depressed and nondepressed groups. Further, the depressed subjects were more external in locus of control orientation. Low self-esteem and somewhat increased feelings of deserving-

[6] When analyses were rerun using the conservative Scheffé procedure to correct for error rate inflation, significant differences between the depressed and nondepressed groups were again found on self-esteem, internal–external control, characterological self-blame, and chance.

ness characterized the depressed population, suggesting that characterological self-blame is esteem related, not control related.

The results would have been considerably more compelling if it were found that those students who were not depressed engaged in more behavioral self-blame than depressed students, yet this was not the case. However, it can perhaps be argued that the behavioral self-blame reported by the depressed and nondepressed populations differed in an important way; for the depressed group the behavioral self-blame co-occurred with characterological self-blame, and blaming one's behavior was thus an extension of blaming one's character. It may be difficult to blame one's character without blaming one's behavior, yet it may be very possible to blame one's behavior without blaming one's character. In the former instance the behavior may be regarded as uncontrollable in that it is a direct and unalterable extension of one's character (i.e., controlled by one's character). In the latter case the behavioral self-blame does not reflect decreased self-esteem, but rather the belief that one's behavior is modifiable. Perhaps behavioral self-blame, when displayed in conjunction with characterological self-blame, is simply a further reflection of characterological self-blame. However, when it occurs alone it is likely to represent an adaptive response, stemming from a desire to maintain a belief in personal control following a negative outcome.

Study 2: Rape[7]

Method

Respondents. Respondents were rape crisis centers located throughout the United States. Center names were derived primarily from a list located in a federal report on rape and its victims (Brodyaga et al., Note 3); this list was supplemented by names of rape crisis centers found in an informal directory at a local women's center. Services that were hotlines only or were task forces without counseling services were excluded from the final list. Questionnaires were mailed to 120 centers representing 37 states and the District of Columbia. Thirty of the questionnaires were returned "addressee unknown." Of the remaining 90 crisis centers, 48 responded (53% return rate; including those returned "addressee unknown," the return rate was 40%).

Questionnaire. In a cover letter I identified myself as a social psychologist interested in the nature of self-blame among victims of rape; letter recipients were asked to base their questionnaire responses on their experiences as counselors of rape victims. The questionnaire items dealt primarily with the issue of self-blame. Crisis centers were asked to indicate approximately how many rape victims they see yearly and of those they see, the percentage who blame themselves, at least in part, for the rape. The behavioral self-blame question asked, "Of the rape victims you see, what percentage blame themselves for the rape because of some behavior (act or omission) they engaged in at the time of or immediately prior to the rape (e.g., 'I should not have walked alone,' 'I should not have hitchhiked,' 'I should have locked my windows')?" The rape crisis centers were then asked to provide specific examples of behavioral self-blame related by the women they have counseled. The characterological self-blame question asked, "Of the rape victims you see, what percentage blame themselves for the rape because of some character trait or personality flaw they believe they have (e.g., 'I am so stupid, I deserved to be raped,' 'I'm the kind of woman who attracts rapists,' 'I am a weak person and can't say no')?" Specific examples of this type of blame were then requested as well. The centers were also asked to indicate on two 7-point scales, with endpoints *almost not at all* and *completely,* how much self-blaming characterized the women who engaged in behavioral and characterological self-blame, respectively; this was included in order to ascertain whether behavioral and characterological self-blamers differ in terms of the amount of self-blame they attribute to themselves for the rape.

Results

Of the 48 rape crisis centers that responded, 38 completed the questionnaire, 6 wrote letters providing general comments, and 4 wrote that they did not provide direct counseling services and were therefore unable to complete the items. Results were therefore based on the completed questionnaires of 38 centers. The rape crisis centers differed markedly in the scope of their operation, with the 3 smallest serving 12, 30, and 40 rape victims yearly, and the 3 largest serving 1,200, 1,250, and 1,500; the mean number of rape victims seen across the centers was 335.

In general, self-blame was reported as quite common; the reported mean percentage of

---

[7] The results of this study were reported by the author at the symposium "New Directions in Control Research" at the convention of the American Psychological Association, Toronto, 1978. The author thanks Chris Eagan for her invaluable help on the project.

women who blamed themselves at least in part for the rape was 74%. Of those who blamed themselves, behavioral self-blame was reported as considerably more common than characterological self-blame, and the differences between the reported incidence of the two blaming strategies was significant, $F(1, 32) = 140.90$, $p < .001$; an average of 69% of the women were reported as blaming themselves behaviorally, whereas an average of 19% were reported as blaming themselves characterologically. Further, examples of the two types of self-blame provided by the rape crisis centers confirmed the fact that they were readily able to distinguish between the two. Frequently mentioned examples of behavioral self-blame included the following: I shouldn't have let someone I didn't know into the house, I shouldn't have been out that late, I should not have walked alone (in that neighborhood), I should not have hitchhiked, I should not have gone to his apartment, I shouldn't have left my window open, I should have locked my car. Examples of characterological self-blame that were frequently reported included: I'm too trusting, I'm a weak person, I'm too naive and gullible, I'm the kind of person who attracts trouble, I'm not a very aware person, I'm not at all assertive—I can't say no, I'm immature and can't take care of myself, I'm not a good judge of character, I'm basically a bad person. It is perhaps worth noting that examples of behavioral blame were, without exception, reported in the past tense (i.e., I should have/should not have), whereas examples of characterological self-blame were presented in the present tense (I am/am not), perhaps implicitly indicating the presumed modifiability/nonmodifiability of factors associated with behavioral and characterological self-blame respectively (cf. Elig & Freize, 1975). However, the examples of the two types of self-blame provided in the questionnaire were consistent with the different tenses reported in the examples of the crisis centers, and this alone could have accounted for the findings. The author did not realize that she had made these distinctions on the questionnaire until the results clearly differentiated between the tenses used for the two types of self-blame. Finally, in responding to how much women blamed themselves for the rape, the centers reported that characterological self-blamers blamed themselves significantly more for the rape than did behavioral self-blamers (3.92 vs. 3.23), $F(1, 25) = 11.29$, $p < .002$.

Discussion

The rape crisis center counselors reported that the majority of rape victims do blame themselves, at least in part, following the rape. However, the focus of this self-attribution is a behavioral act or omission engaged in at the time of (or immediately preceding) the rape. Fewer than one-fifth of the women served by the centers blamed themselves in a characterological way, evidence that the "popular" view of the masochistic rape victim who perceives herself as worthless is largely unfounded. Rather, the self-blame in which most rape victims engage may represent a control maintenance strategy, a functional response to a traumatic event. Given the large discrepancies between those who blame themselves behaviorally and characterologically, it follows that most women clearly blame themselves in a behavioral manner only and do not combine this response with characterological self-blame, as may be the case with depressives (see above). In suggesting that behavioral self-blame reflects a positive impulse in rape victims, there is no intention of implying that the rape was the woman's fault. It is even likely that the woman who engages in behavioral self-blame does not do so to the exclusion of blaming the rapist, society, or other factors. These blame attributions, instead, would stem from different motivations, control maintenance being the motivation behind self-blame.

Two potentially serious objections to this study require a response. First, many of the women who volunteer or work in rape crisis centers may be ardent feminists who would be more likely to indicate that women blame themselves behaviorally rather than characterologically, for the latter suggests that women see themselves as worthless. In response, if the crisis center workers truly wanted to present women in a positive light,

they would have indicated quite simply that women infrequently blame themselves. Further, there was nothing in the questionnaire or cover letter to indicate that one type of self-blame was "healthier" than another, and several counselors commented that they had never before distinguished between types of self-blame but that it appeared interesting to them. Comments by the counselors indicated that these women were concerned about the health of the women they served and that preserving a positive image of womanhood in general was clearly not central to their activities as rape counselors. The second criticism that could be raised is potentially more serious. It is that women who go to rape crisis centers are most likely to be individuals who do not blame themselves characterologically and do not feel they deserved to be raped. Thus, there is a self-selected population of behavioral self-blamers served by rape crisis centers. It is difficult to counter this claim, for there is probably much truth to it. One must realize, however, that the literature written on rape is almost entirely derived from women who seek help after rape and not from women who quietly keep the trauma to themselves, ashamed to talk about it or admit it. The pervasiveness of self-blame documented in the rape literature is drawn primarily from observations of women at rape crisis centers, from women's centers, or from women who agree to be interviewed by researchers, also a population likely to be self-selected. Thus, the negative image of the rape victim engaging in masochistic, maladaptive self-blame derives from a rape victim population likely to be very similar to that served by the rape crisis centers surveyed. It might also be mentioned that those women who have least difficulty coping with the rape and who are apt to be behavioral self-blamers are probably also missing from the rape center population, for they may not require help (outside their own circle of family and friends) following the rape. Perhaps it is sufficient to point out that within the population of women served by rape crisis centers, self-blame has been improperly understood as self-derogating, reflecting the woman's belief in her own worthlessness, rather than as a response that reflects a positive attempt to reestablish personal control.

General Conclusions and Implications

Self-blame appears to be a label for two very different self-attributions, characterological self-blame being esteem related, and behavioral self-blame being control related. Self-blame as a predictor of good coping and self-blame as a concomitant of depression are no longer inconsistent in light of the two types of self-blame. Further, the paradox in depression—that individuals are simultaneously helpless and self-blaming—can be resolved if characterological self-blame characterizes depressives and differentiates them from nondepressed individuals. The division of self-blame into two different phenomena even has political or cultural implications, for self-blame by a victimized group such as rape victims can now be understood in such a manner as to preclude the perpetuation of a negative image of the group in question. It is perhaps unfortunate that one term has been used as a label for these two different self-attributions, for the singular term *self-blame* blurs important distinctions between adaptive and maladaptive responses to failures and victimizations. Since popularly the term has negative connotations, it would perhaps be desirable to provide a more neutral label for behavioral self-blame. Particularly in the case of rape, this would render more politically palatable the proposition that behavioral self-blame is of functional value for victims of rape.

The recognition of two types of self-blame may have therapeutic implications. Seligman's (1975) control-oriented strategies continue to seem appropriate for depressives, whose self-blaming does not imply high perceived control, but rather lack of control. Further, a cognitive therapy that entails reattributing the focus of one's attributions (e.g., from character to behavior) might be of value in treating depressives. In general, leading people to focus on behaviors that are alterable, rather than on their relatively nonmodifiable, more global character, may increase perceived future avoidability of negative events and

perceived control in general, outcomes that would presumably be of positive value. Dweck's (1975) successful reattribution training with helpless students, involving reattributing their ability attributions for failure to effort attributions, suggests the potential of such cognitive strategies using self-blame.

In the case of rape, the control concerns that may be implicit in the rape victim's self-blame often seem to be ignored in counseling, not because they are regarded as unimportant, but because they may go unrecognized. One counseling technique for rape victims includes repeatedly telling a woman that there is nothing she could have done to avoid the rape, that it was entirely the rapist's doing and outside of her control. Although meant to be reassuring, these statements could conceivably be not at all helpful, in light of the proposition that the women are seeking to reestablish a sense of control. Rather, counselors should perhaps recognize the functional value of behavioral self-blame and concentrate on enabling the victim to reestablish a belief in her relative control over life outcomes (e.g., discussing possible ways of minimizing the likelihood of a future rape). Too often, behavioral self-blame is regarded as detrimental to mental health. Rather, it may serve as an indicator of the victim's psychological needs at the time.

Behavioral and characterological self-blame appear to be distinct reactions yet are far from fully understood. Ideas raised in this paper have been tested only with female subjects and thus may not generalize to other populations; this issue of generalizability particularly calls for research with male subjects. Further, the relationship between the two types of self-blame would appear to be a fruitful area for future study. Does behavioral self-blame that occurs with characterological self-blame, for example, lose its adaptive value, or is it similar to behavioral blame that occurs without characterological self-blame? Is characterological self-blame that occurs without behavioral self-blame more or less maladaptive than characterological self-blame that occurs with behavioral self-blame? In addition, longitudinal studies designed to tap the coping implications of these two types of self-blame would be important contributions to our understanding of the relationship between coping and attributional strategies. Another possible direction lies in the area of blaming strategies by help-givers. Brickman and his colleagues (Brickman et al., Note 4) have presented a compelling case for the psychological tensions that exist between conditions that render helping appropriate (i.e., regarding the recipient of help as not responsible) and conditions that render helping effective (i.e., attributing responsibility to the recipient of help). That is, one is apt to help an individual who is not to blame for a misfortune, yet this attribution minimizes the belief that one's help will be effective. Perhaps training both help-givers and recipients of help to hold behavioral blame orientations (as opposed to characterological blame orientations) would help resolve the existing tensions. Last, the therapeutic implications of the two types of self-blame—behavioral and characterological—remain an area ripe for future study.

Explaining Attributions for Achievement: A Path Analytic Approach

William M. Bernstein
University of Texas at Austin

Walter G. Stephan
New Mexico State University

Mark H. Davis
University of Texas at Austin

A nonmotivational, expectancy-confirmation model of asymmetrical achievement attributions is compared with a theory of attributional egotism. Data permitting tests of the theories and comparisons between them were collected over an entire semester from students taking examinations in a large undergraduate course. Students provided expectancies, bases for expectancies, and attributions for three examinations. It was found that students' expectancies were unrealistically high at the beginning of the course but became more accurate over time. Path analysis indicated that expected scores were based on prior performance and, increasingly throughout the semester, on expected effort. Analysis of variance further revealed that subjects were generally egotistical in their outcome attributions, stressing internal factors following success and external ones following failure. Attributions were also influenced by the degree to which expectancies were confirmed if such expectancies were clearly based on the attribution factor in question.

Are attributions for achievement biased by a motive to protect and enhance self-esteem? Bradley was more satisfied in 1978 that the existence of the motive had been demonstrated than Miller and Ross were in 1975. Both reviews sensibly concluded, however, that probably motivational and cognitive factors together determine attributions. "The challenge remains," said Miller and Ross (1975), "for future researchers to assess the relative explanatory values of the motivational and nonmotivational interpretations of assymetrical attributions." The present investigation, which focuses on the attributions students make for their performance on examinations, attempts such a comparison of cognitive and motivational theories. Specifically, a cognitive model maintaining that attributions for exam performance are a function of expectancy confirmation is compared with an egotism model holding that good outcomes should be attributed internally and bad outcomes externally, regardless of expectancy confirmation.

The expectancy-confirmation model, first proposed by Miller and Ross (1975), is derived from Heider's (1958) common sense theory of action. According to Heider, an outcome that disconfirms an expectancy calls the basis of that expectancy into question. Miller and Ross assume that in achievement situations people generally expect and intend to succeed. If these high expectations are based on the individuals' beliefs that they possess the appropriate skills and will exert sufficient effort, then success will be attributed to the internal factors of ability and effort. Failure, on the other hand, disconfirms high expectations, weakens the individuals' faith in the internal bases for those expectations, and leads to external attributions such as luck and task difficulty.

The authors thank Frank Bean, John Loehlin, Melvin Snyder, and Robert Helmreich for commenting on earlier versions of this manuscript. This study was supported by a grant from the Hogg Foundation for Mental Health to the second author.

A comparative analysis of expectancy confirmation and egotism involves two types of inquiry. We must not only decide how well the models predict attributions in situations where we know their preconditions are satisfied (cf. Stephan, Bernstein, Stephan, & Davis, 1979, Experiment I), but we must also consider whether the models' preconditions themselves are likely to obtain in real achievement contexts. Egotism is a simple theory, applicable in most any situation where performance is relevant to self-esteem (Snyder, Stephan, & Rosenfield, 1978). Expectancy confirmation, on the other hand, is built upon a more complex set of interlocking assumptions.

The present study analyzed students' attributions for their own performance on academic examinations. We think it safe to assume that test performance is relevant to students' self-esteem and hence that egotism can make meaningful predictions of attributions in the examination context. Whether students' expectations for exam performance tend to be high and based on internal factors seems less certain. Our analysis will therefore focus first on verifying the assumptions of the expectancy–confirmation theory.

Two previous studies, both conducted in university exam settings, have measured expectations for success and bases of expectations. Simon and Feather (1973) asked students to estimate their chance of passing an upcoming exam and to rate the anticipated contributions of ability, effort (study), test difficulty, and luck on their future performance. Although high expectations of passing the exam did tend to be based on internal factors (ability and effort), the expectations did not appear to be especially high. The mean rating of confidence of passing the exam was "moderate," and 80% of all students did actually pass. Davis and Stephan (in press) examined expectancies and their bases in two separate classrooms. While the expectancies of students in both classes were overoptimistic (combined mean expected score 88%; actual score 80%), expectations in one class were strongly based on ability alone and expectations in the other were weakly related only to effort.

The results of past research do not provide clear answers to our questions about the assumptions of the expectancy-confirmation model. The present study, which examined students' expectations, their bases, and attributions over the course of an entire semester, was designed to exploit more fully the potential of the university field setting. Students from a large introductory psychology course completed questionnaires before and after each of three examinations given over the course of a semester. For each exam students reported their expected scores and the bases for these expectancies; then, after the exam, they made attributions for their actual performance. The acquisition of expectancies, their bases, actual performance, and attributions for three successive exams allows us to chronicle potential changes in these variables stemming from increasing exam experience and feedback. Path analysis (Duncan, 1966; Wright, 1921) will be used to plot the relations between the variables across the three tests.

The decision to use path analysis was based largely on two factors. First, the path approach adds graphic, descriptive continuity to the flow of related events. Second, path analysis makes it possible to examine a number of potentially significant determinants of expectations that have been ignored in previous research. Simon and Feather (1973) and Davis and Stephan (in press) examined only the four attribution factors of Weiner, Frieze, Kukla, Reed, Rest, and Rosenbaum (1971). It seems likely, however, that previous performance, previous expectations, and attributions for previous performance would also affect subsequent expectations.

After the presentation of the path model, the need for refining the expectancy-confirmation predictions of posttest attributions will be discussed. Additional analyses designed to assess the relative merits of the refined cognitive model and egotism will then be presented.

Path Analysis Method

Subjects

The subjects were 469 undergraduates enrolled in an introductory psychology class at the University

of Texas at Austin. Grades in the course were based on scores obtained on three out of four multiple choice tests administered during the semester. Pretest expectations and posttest attributions were collected for the first three tests given.

Pretest Questionnaire

Immediately before each test was administered, a short questionnaire was given to each student. Subjects were asked what score (0% to 100%) they expected to obtain on the test. They were also asked to judge the anticipated effect of ability, effort (study), test difficulty, and luck on their upcoming performance in the following manner. First they indicated whether a factor would help or hinder performance. They then estimated the extent to which the factor would influence performance on a 10-point scale running from *will slightly influence* to *will greatly influence*. If the student marked that a factor would hinder performance, the amount the factor was judged to influence performance was given a negative value. If a factor was expected to help performance, a positive value was assigned.

Posttest Questionnaire

During the first class period following the exam, each student was provided with a second questionnaire that included his or her actual percentage score on the exam as well as the predicted score. Students were asked to make attributions for their actual performance, using the same four causal factors that appeared on the pretest questionnaire. Again, helping factors were scored positively and hindering factors negatively.

Model Construction

The intercorrelations of bases of expectation, expected score, actual score, and attributions were studied by means of a path model. In path analysis it is assumed that there is a weak causal ordering among the variables. In the present study, the temporal sequence in which the questionnaires were administered (which followed the temporal sequence of real events) was used as the basis for causal ordering of the variables. Only one ordering decision could not be made by appealing to the questionnaire order. This involved the precedence of expected score and basis of expected score on the pretest questionnaires. The assumption was made that bases of expectancy precede expectations. The ordering of variables in the model then is: bases of expected score for test one, expected score for test one, score for test one, attributions for test one outcome, bases of expected score for test two, expected score for test two, score for test two, and so on. Given the large number of variables considered, the original model from which Figure 1 was derived did not include estimates of every possible path. The criteria used to construct the original model were as follows:

1. No paths were calculated *between* pretest bases of expectations or between posttest attributions (e.g., no path was estimated between effort expectations and ability expectations, or between effort attributions and ability attributions).

2. The only paths estimated from a given basis of expectancy were to (a) the immediately following expected score, (b) the immediately following actual score, (c) the immediately following attribution, and (d) the next basis of expectancy (e.g., paths were considered from XEF2 to XSCOR2, SCOR2, ATEF2, and XEF3).[1]

3. The only paths estimated from a given expected score were to (a) the actual score for which the expectancy was made, and (b) the immediately following expected score (e.g., paths estimated from XSCOR1 were to SCOR1 and XSCOR2 only).

4. The only paths estimated from an actual score were to (a) the following scores, (b) the immediately following expected score, (c) the immediately following attributions, (d) the bases of the next expected score (e.g., paths were estimated from SCOR1 to SCOR2, SCOR3, XSCOR2, ATEF1, ATAB1, ATTD1, ATLK1, XEF2, XAB2, XTD2, XLK2).

5. The only paths estimated from a given attribution were to (a) the immediately following score, (b) the immediately following expected score, (c) the immediately following basis of expectancy, and (d) the next attribution (e.g., paths were estimated from ATEF1 to SCOR2, XSCOR2, XEF2, ATEF2).

Paths were trimmed from the model constructed by the above criteria if the probability level of their associated F ratios was greater than .05 (Kerlinger & Pedhazur, 1973, p. 318). If a path was deleted from the original model, we assumed for the sake of parsimony that the contribution of the nonsignificant predictors was zero and performed new regressions with only the significant predictors included to obtain the path coefficients. A complete correlation matrix for all the variables in the model appears in Table 1. Means and standard deviations for the variables are in Table 2. The path analysis was based on data collected from the 179 students from the entire class who responded to all six questionnaires. Generalization from the restricted population seems justified, since the distribution of all scores and all expected scores for both the restricted group and the entire population is substantially the same.

---

[1] The symbol system used to refer to the variables in Figure 1 is straightforward. The prefix X stands for an expectancy. It is used in conjunction with both expected scores (XSCOR) and expected effects of a factor like ability (XAB). The numerical suffixes 1, 2, and 3 indicate the test for which the variable is relevant. Hence, XSCOR1 would be the expected score for Test 1; XEF2 would be the expected effect of effort or study on Test 2 performance. Attributions for performance are indicated by the prefix AT. For example, attributions to the task difficulty factor for Test 3 are symbolized ATTD3. Attributions to ability, luck, and effort for Test 2 performance would be indicated by ATAB2, ATLK2, and ATEF2, respectively. Actual scores are indicated as follows: Test 1 actual score is SCOR1; Test 2 is SCOR2; Test 3 is SCOR3.

Note. $n = 179$. (XSCOR1, XSCOR2 and XSCOR3 are student's expected scores for Tests 1, 2, and 3, respectively. SCOR1, SCOR2, and SCOR3 are the actual scores achieved. XEF1, XEF2, and XEF3 are the expected effects of effort [study] on Test 1, 2, and 3 performance, respectively. XAB1, XAB2, and XAB3 are the expected effects of ability on Test 1, 2, and 3 performance, respectively. XTD1, XTD2, and XTD3 are the expected effects of test difficulty on Test 1, 2, and 3 performance. XLK1, XLK2, and XLK3 are the expected effects of luck on Tests 1, 2, and 3. ATEF1, ATEF2, and ATFE3 are effort attributions for the three tests. ATAB1, ATAB2, and ATAB3 are ability attributions. ATTD1, ATTD2, and ATTD3 are test difficulty attributions. ATLK1, ATLK2, and ATLK3 are luck attributions.)

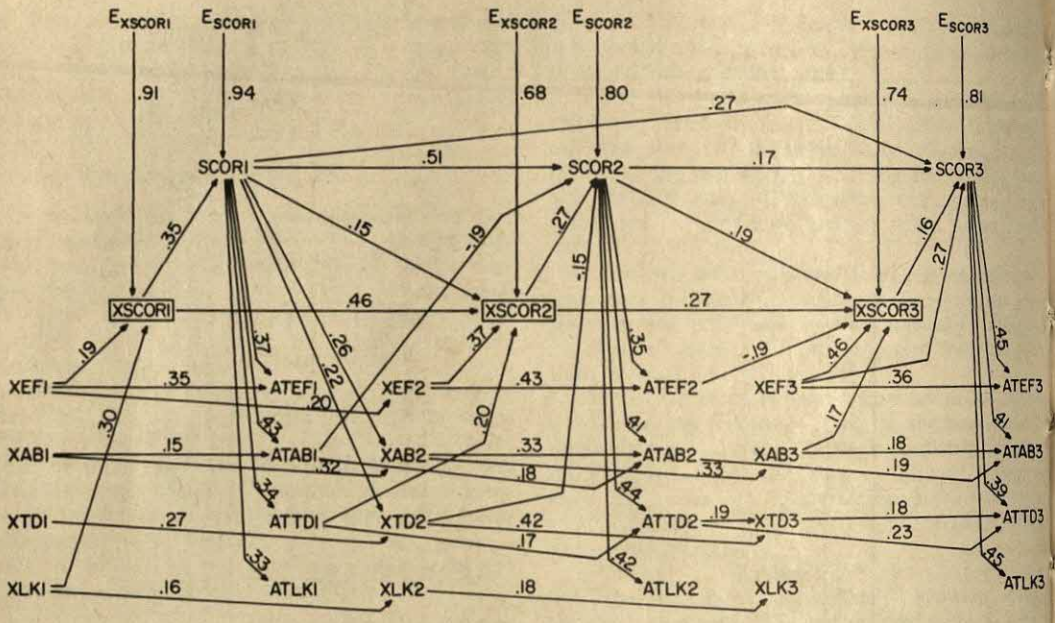

Figure 1. Path Model. ($n = 179$. XSCOR1, XSCOR2 and XSCOR3 are students' expected scores for Tests 1, 2, and 3, respectively. SCOR1, SCOR2, and SCOR3 are the actual scores achieved. XEF1, XEF2, and XEF3 are the expected effects of effort [study] on Test 1, 2, and 3 performance, respectively. XAB1, XAB2, and XAB3 are the expected effects of ability on Test 1, 2, and 3 performance, respectively. XTD1, XTD2, and XTD3 are the expected effects of test difficulty on Test 1, 2, and 3 performance. XLK1, XLK2, and XLK3 are the expected effects of luck on Test 1, 2, and 3. ATEF1, ATEF2, and ATEF3 are effort attributions for the three tests. ATAB1, ATAB2, and ATAB3 are ability attributions. ATTD1, ATTD2, and ATTD3 are test difficulty attributions. ATLK1, ATLK2, and ATLK3 are luck attributions.)

Examination of Expectations

Before presenting the path analysis results, we can examine the assumption made by Miller and Ross that expectancies in achievement situations tend to be relatively high. An inspection of the discrepancies between the students' expected and actual scores indicates that whereas they initially overestimated their actual scores by a considerable margin, they became increasingly accurate across the three tests (Table 2). Test 1 predictions showed an overestimation of 9 points. By Test 2, students were still overestimating their scores but this time by only 5 points, significantly more accurate than on Test 1, $t(178) = 4.09$, $p < .001$. By Test 3, expected–actual discrepancy was less than 1 point, and the error consisted of an underestimation of performance. Test 3 expectations were significantly more accurate than those for Test 2, $t(178) = 5.01$, $p < .001$.

Path Analysis Results [2]

Bases of Expectations

Across the three tests there is an increased reliance on perceived study (and to a lesser degree on perceived ability) as a basis of expectation (Figure 1). Whereas the overoptimistic Test 1 expectations were primarily based on luck and to a lesser extent on study, the more realistic expectations for Tests 2 and 3

[2] Interpretation of changes in path coefficients is more meaningful when we can safely assume that the structure of the causal system regulating the variables in a model remains constant over time. Structural stability between explicitly considered variables is, however, typically accompanied by stability among latent, unanalyzed sources of variability. Since stable latent variables create correlations among the residuals of explicit variables, the existence of a constant factor structure over time practically assures some violation of path model assumptions concerning disturbance terms (see Heise, 1970).

Table 2
Means and Standard Deviations for the Variables in the Path Model

Variable	*M*	*SD*	Variable	*M*	*SD*	Variable	*M*	*SD*
XEF1	5.91	5.42	XEF2	3.53	7.00	XEF3	3.02	6.76
XAB1	6.21	3.59	XAB2	4.23	4.82	XAB3	3.97	5.37
XTD1	2.28	7.30	XTD2	−1.28	7.78	XTD3	−0.26	7.44
XLK1	2.70	4.33	XLK2	1.93	5.30	XLK3	2.45	4.86
XSCOR1	81.89	7.30	XSCOR2	75.78	10.15	XSCOR3	74.02	12.55
SCOR1	72.72	11.11	SCOR2	70.82	11.01	SCOR3	74.78	11.73
SCOR1–XSCOR1	−9.17	10.92	SCOR2–XSCOR2	−4.96	11.56	SCOR3–XSCOR3	0.77	13.07
ATEF1	1.88	7.18	ATEF2	1.38	7.07	ATEF3	1.97	6.88
ATAB1	1.44	6.48	ATAB2	2.42	5.46	ATAB3	3.47	5.33
ATTD1	−4.37	6.24	ATTD2	−3.94	6.11	ATTD3	−1.70	6.56
ATLK1	−1.73	4.16	ATLK2	−0.51	4.72	ATLK3	0.91	4.78

Note. $n = 179$. (XSCOR1, XSCOR2 and XSCOR3 are students' expected scores for Tests 1, 2, and 3, respectively. SCOR1, SCOR2, and SCOR3 are the actual scores achieved. XEF1, XEF2, and XEF3 are the expected effects of effort [study] on Test 1, 2, and 3 performance, respectively. XAB1, XAB2, and XAB3 are the expected effects of ability on Test 1, 2, and 3 performance, respectively. XTD1, XTD2, and XTD3 are the expected effects of test difficulty on Test 1, 2, and 3 performance. XLK1, XLK2, and XLK3 are the expected effects of luck on Tests 1, 2, and 3. ATEF1, ATEF2, and ATEF3 are effort attributions for the three tests. ATAB1, ATAB2, and ATAB3 are ability attributions. ATTD1, ATTD2, and ATTD3 are test difficulty attributions. ATLK1, ATLK2, and ATLK3 are luck attributions.)

were directly and strongly related to perceived study. Previous expectations also played a role in determining subsequent expectations, although their influence diminished over the semester (from .46 to .27) as expectations became more accurate. No paths were found between anticipated ease or difficulty of any test (XTD) and expected score, but task difficulty attributions for Test 1 performance (ATTD1) were positively related to Test 2 expectancies. That is, students who said the ease of Test 1 aided Test 1 performance tended to predict higher scores for Test 2.

The basis-of-expectation results differ from those of Simon and Feather (1973) and Davis and Stephan (in press) in that effort emerged as a much stronger determinant than ability. There is at least one important difference in procedure that may account for the discrepancy between those studies and the present study. In the earlier studies, previous expectation and previous performance were not entered into the regression equations. When the path coefficients for XSCOR2 are calculated omitting XSCOR1 and SCOR1 as predictors, the path from effort to XSCOR2 remains unchanged, whereas the ability path shows a sizable increase (from .09 to .21). These findings suggest that had previous studies investigated the role of past expectancy and performance on subsequent expectations, the role assigned to perceived ability as a basis of expectations would have been smaller.

Despite the significantly larger paths from effort to expectancy than from ability to expectancy, the mean perception (Table 2) of ability's anticipated effect on performance was somewhat larger than that of effort for every test. That is, although most students said their ability would help them perform well on

Two types of analyses performed on the present data indicate that while factor constancy does exist, the accompanying violation of disturbance assumptions is minimal. Factor analyses performed on the 10 variables represented at each of the three time periods all yielded highly similar three-factor solutions. Accordingly, analysis of residuals revealed significant (though generally small) intercorrelations among disturbance terms within each time period. On the other hand, correlations between the residuals of the same dependent variable measured at separate time points (e.g., ATEF1, ATEF2, and ATEF3) were negligible. Note the lack of correlation between the error terms, $E = (1 - R^2)^{\frac{1}{2}}$, associated with expected and actual scores. These results indicate that an acceptable compromise between the assumptions of structural constancy and uncorrelated errors exists in these data. Thus, while the usual caveats relevant to inferring causality from correlational data of course apply here, violations of the particular assumptions of time series analysis seem minimal.

the tests, only those who thought that they had studied hard actually predicted high scores.

Determinants of Performance

The two factors that were consistently related to actual outcome for Tests 2 and 3 were the expected scores for the tests and performance on the previous test(s). For Test 1 expected score was the only significant antecedent of performance, and the size of the expectancy–performance relation is larger than that for subsequent tests. This makes sense if it is assumed that students' expectations for the initial test include information about performance on similar tasks in the past. XSCOR1 as a predictor of SCOR1 may then be thought of as confounding the two elements that are discretely represented by SCOR1 and XSCOR2 as predictors of SCOR2, and SCOR1/SCOR2 and XSCOR3 as predictors of SCOR3.

Other predictors of actual performance were ability attributions (ATAB1) and anticipated effect of test difficulty (XTD2) for SCOR2, and the anticipated effect of study (XEF3) for SCOR3. Test 1 ability attributions and the expected role of test difficulty were both negatively related to performance on Test 2. Taken together, these two findings may be indicative of complacency among students who attributed high Test 1 scores to ability and those who expected Test 2 to be easy. Both types of inference could conceivably have led to poor performance on Test 2. The positive relation between the anticipated beneficial influence of study (XEF3) on Test 3 performance and actual performance seems straightforward.

Determinants of Attributions

The results clearly show that all four attributions were related to actual performance in a logical manner, that is, they were perceived to have facilitated high scores and hindered low scores. In addition, for attributions to internal factors it was found that the expected contribution of these factors was related to subsequent attributions to them. Thus, if the subjects expected effort (and to a lesser extent, ability) to help them, they subsequently attributed their outcome to that factor. This was not the case for luck on any of the three tests. The expectancy–attribution relation was obtained for task difficulty, the other external factor, only for Test 3 (the path between XTD3 and ATTD3).

The existence of direct paths from internal bases of expectancy to attributions (unmediated by outcome) suggests that to some degree students do not alter their pretest opinions of the expected contributions of their ability and effort to test performance, even after performance feedback. Since the internal factors are knowable to a greater extent before the test than the external factors are, one might expect more pretest–posttest consistency for internal than external factors.

Attribution, Future Expectations, and Future Performance

Attributions for performance had few effects on future expectations, the bases of these expectations, or future performance. We expected attributions at least to affect bases of expectations (e.g., ATEF1 was expected to influence XEF2, ATAB1 was expected to influence XAB2, etc.). Only one such relationship was found, the path between ATTD2 and XTD3, and it was relatively small. Where attributions did affect expected scores and actual performance, their influence was not mediated by the bases of expectancy variables (e.g., ATTD1 did not affect XTD2, which in turn affected XSCOR2; rather, ATTD1 affected XSCOR2 directly). Three such direct relationships were found, and they comprised the entire influence of attributions on future expectancy and actual performance. The paths were between ATAB1 and SCOR2 (−.19), ATEF2 and XSCOR3 (−.19), and ATTD1 and XSCOR2 (.20).

The small effect of attributions on expectancies is surprising given the important role assigned to them in both Weiner's (1974) model and the recent learned helplessness formulation (Abramson, Seligman, & Teasdale, 1978). More detailed analysis of the role of attributions in expectancy formation seems warranted by these results.

Reformulation and Test of the Expectancy Model

The path model and the associated table of means suggests that a revision of the dual assumptions of the expectancy-confirmation approach to attribution is needed. Initially, people tend to believe that they will be lucky and are overoptimistic regarding their chances for success. Later, the more experience students gain with a task and the more accurate their expectations become, the more expectancies are based on internal factors, especially effort.

Given what we have learned about students' expectations and their bases, we can now make more specific predictions concerning the role of confirmation of expectations on attributions.

1. Confirmation will exert an effect on effort attributions for Tests 2 and 3 performance, since expectations were largely based on perceived study for these two tests. Confirmed expectancies should be attributed to effort more than disconfirmed expectancies.

2. Ability and task attributions should be minimally affected by confirmation since expectations were not based on either of these factors.

3. Previous research has consistently shown that unexpected outcomes are attributed more to luck than expected outcomes (McMahon, 1973; Simon & Feather, 1973; Stephan et al., 1979). We expect to find a similar result in this study for all three tests, regardless of whether or not luck was a significant predictor of expected score (as for Test 1).

The prediction of differential effects of the confirmation factor on effort (disconfirmation leading to less attribution) and luck (disconfirmation leading to more attribution) is logical. If one knows he/she has worked hard, that knowledge is not easily changed by receipt of a low grade. Rather, the perceived effect of study merely becomes discounted as a cause of poor performance relative to its role in explaining good performance. Judgments of luck's influence on performance, however, are directly related to the element of surprise and should not be affected by whether or not luck formed the basis of expectation. Disconfirmation of a positive or negative nature seems to automatically imply the operation of a greater amount of capriciousness and luck in the production of outcomes than does confirmation.

The predictions of the egotism model are, of course, not altered by the path model information, since they do not depend upon expectations or bases of expectations. The motivational model simply predicts that the internal factors of ability and effort will be seen as causing good performance and the external factors of task difficulty and luck will be seen as the causes of poor performance on all three tests.

Analysis of Variance Method

In order to test the above predictions and to contrast the effects of expectancy confirmation and egotism on attributions, we separately analyzed the attributions following each test according to a simple 2(Level of Expectancy) × 2(Confirmation of Expecancy) design. Students were informed at the beginning of the semester and on our pretest questionnaire that scores of 85%–100% constituted an A, 75–84 a B, 60–74 a C, 50–59 a D, and 49 and below an F. Students whose expected score for a given test was 75% or above made up the high expectancy group for that test. Those whose expected score was 74% or below made up the low expectancy group. Students with high expectancies whose scores were 75 or above and those with low expectancies whose scores were 74 or below made up the confirmation of expectancy groups. Students with low expectancies who scored 75 or above and those with high expectancies who scored 74 or less made up the disconfirmation groups.

A different method for scoring the attribution questions was used for this analysis than was employed for the path model (see Path Method). In order to study the interaction between expectancy and performance (i.e., the confirmation factor), the scoring of the attributions was modified to take into account the relationship between the perceived effect of a factor (did it contribute to the outcome or not) and the valence of the outcome (success or failure). Accordingly, when the rating indicated that the subject felt his outcome, high performance or low performance, could be attributed to a given factor, its rating was scored positively. If a factor was perceived to work in the direction opposite from the subject's ultimate outcome, it was scored negatively (Stephan et al., 1979; Stephan, Rosenfield, & Stephan, 1976). Thus, when the subject succeeded, all factors the subject perceived as having helped him were scored positively, and all hindering factors were scored negatively. When he failed, hindering factors were scored positively, and helping factors negatively. The reason for reversing the directionality

Table 3
Expected Scores, Actual Scores, and n *of Subjects*

Expectancy	Confirmed			Disconfirmed		
	Expected score	Actual score	*n*	Expected score	Actual score	*n*
			Test 1			
High	85.7	82.7	158	82.6	63.5	157
Low	66.4	61.2	41	66.6	78.9	10
			Test 2			
High	83.1	83.1	108	80.8	63.6	119
Low	64.2	60.1	109	66.4	79.5	28
			Test 3			
High	83.1	84.3	123	80.5	66.7	68
Low	61.9	62.5	85	66.0	81.0	54

of the scoring for subjects who failed is derived from Kelley's (1971) analysis of facilitatory and inhibitory causes. Facilitative causes are those that make the outcome more likely, whereas inhibitory causes tend to prevent the occurrence of certain outcomes. For example, high ability facilitates success but inhibits failure. Similarly, low ability facilitates failure and inhibits success. The scoring system, then, scores facilitative causes positively and inhibitory causes negatively.

Analysis of Variance Results [3]

Table 3 shows the results of the group assignment procedure for the three examinations. Three separate Expectancy × Confirmation analyses of variance (ANOVAS) show that the mean expected score of the high expectancy groups is significantly greater than that of the low expectancy groups, as planned. Test 1: $F(1, 362) = 321.43$, $p < .001$; Test 2: $F(1, 360) = 424.53$, $p < .001$; Test 3: $F(1, 326) = 590.41$, $p < .001$. In addition, high expectancy – confirmation and low expectancy – disconfirmation students on Tests 2 and 3 have higher expected scores; Test 2: $F(1, 360) = 7.57$, $p < .01$; Test 3: $F(1, 326) = 21.25$, $p < .001$.

The confirmation group assignment was equally effective. Subjects in the confirmation cells had significantly smaller absolute discrepancies between their expected and actual scores for all three tests than did students in the disconfirmation conditions. Test 1: $F(1, 362) = 33.65$, $p < .001$; Test 2: $F(1, 360) = 91.51$, $p < .001$; Test 3: $F(1, 326) = 111.22$, $p < .001$. There were three other significant effects observed for discrepancy scores. On Tests 1 and 2, high expectancy – confirmation and low expectancy – disconfirmation students tended to be more accurate with their predictions than were students in the other conditions; Test 1: $F(1, 362) = 16.08$, $p < .001$; Test 2: $F(1, 360) = 14.11$, $p < .001$. On Test 3, low expectancy subjects tended to be more accurate than were high expectancy subjects, $F(1, 326) = 4.69$, $p < .05$.

Attribution measures. Egotism would predict a greater emphasis on internal factors given success (high expectancy – confirmation and low expectancy – disconfirmation) than would occur given failure (low expectancy – confirmation and high expectancy – disconfirmation). The opposite pattern of results would be predicted for external factors. Attributions in accordance with these predictions would result in a Level of Expectancy × Confirmation interaction. As predicted, attri-

[3] All analyses used the Statistical Package for the Social Sciences (SPSS) ANOVA regression model, given the unequal cell *n*s. Also note that each of these analyses included any subjects who made a prediction and took the test relevant to the specific analysis. Hence, the *n*s vary for each analysis. This also means that the population assessed in these ANOVAS includes extra subjects whose data were not used to calculate the path model. Similar ANOVAS carried out on the restricted population used to construct the path model yielded substantially the same pattern of results as that obtained from the total population, although significance levels varied somewhat.

butions for Test 1 performance (Table 4) exhibit egotism effects for all four factors. The Expectancy × Confirmation interaction for all four factors and for an internal minus external composite (Stephan et al., 1976) were all highly significant: Effort $F(1, 349) = 5.17$, $p < .05$; ability $F(1, 356) = 13.16$, $p < .001$; task $F(1, 351) = 30.15$, $p < .001$; luck $F(1, 356) = 4.43$, $p < .05$; internal–external $F(1, 334) = 58.93$, $p < .001$. Ability and effort, the internal factors, were emphasized as the causes of good outcomes, whereas task difficulty and luck, the external factors, were perceived to be the cause of poor performance.

The only other significant effect for Test 1 was the predicted emphasis on luck by students whose expectations were disconfirmed, $F(1, 354) = 4.98$, $p < .05$.

Attributions for Test 2 also generally confirmed predictions. The egotism interaction again emerged for three of the four factors and the composite: Effort $F(1, 353) = 19.04$, $p < .001$; ability $F(1, 351) = 68.58$, $p < .001$; task $F(1, 353) = 69.18$, $p < .001$; internal–external $F(1, 335) = 116.68$, $p < .001$. Luck attributions, however, did not show a motivational effect. Effort attributions were influenced more by the confirmation factor, as predicted. Confirmed expectancies were attributed more to effort, the basis of expectations, than were disconfirmed expectancies, $F(1, 349) = 4.47$, $p < .05$. Luck attributions were again influenced by confirmation, with disconfirmation subjects stressing luck more than confirmation subjects, $F(1, 354) = 13.65$, $p < .001$. The composite measure was also influenced by the confirmation variable. Disconfirmed expectancies led to a greater reliance on external than on internal factors, $F(1, 335) = 12.19$, $p < .001$.

Attributions for Test 3 showed egotism effects on all five dependent variables: Effort $F(1, 321) = 36.69$, $p < .001$; ability $F(1, 320) = 106.69$, $p < .001$; task $F(1, 314) = 17.52$, $p < .001$; luck $F(1, 317) = 5.01$, $p < .05$; internal–external $F(1, 303) = 136.75$, $p < .001$. Confirmation again resulted in a greater reliance on effort than did disconfirmation, as predicted, $F(1, 312) = 5.43$, $p < .05$. Again, luck attributions—and, surprisingly, task attributions—were emphasized by subjects whose expectations were disconfirmed following Test 3: Luck $F(1, 317) = 15.72$, $p < .001$; task $F(1, 314) = 4.51$, $p < .05$. As on Test 2, summed external factors were stressed more than internal factors by disconfirmation subjects, $F(1, 303) = 20.92$, $p < .001$.

Table 4
Attributions to Effort, Ability, Task Difficulty, Luck, and Internal–External Factors

Attribution	High expectancy (A or B)		Low expectancy (C or less)	
	Confirmed	Disconfirmed	Confirmed	Disconfirmed
Effort				
Test 1	5.1	.9	1.8	3.2
Test 2	5.1	−.2	1.3	3.2
Test 3	5.9	.2	1.2	3.8
Ability				
Test 1	4.5	1.4	−.9	3.7
Test 2	5.1	−.1	−.2	5.4
Test 3	5.2	−1.4	−1.7	4.0
Task				
Test 1	−2.3	6.0	4.1	−.8
Test 2	−1.1	6.0	5.5	.9
Test 3	1.0	5.4	2.8	1.3
Luck				
Test 1	−.2	2.9	2.4	2.5
Test 2	1.0	2.7	1.5	3.8
Test 3	2.1	5.4	2.8	3.7
Internal–external				
Test 1	11.9	−6.9	−7.0	5.9
Test 2	10.0	−8.8	−5.9	3.7
Test 3	8.2	−12.4	−6.3	2.7

Note. Expectancy is rated according to test grade anticipated (A, B, C, or less).

Discussion

These results help to define the boundaries of two major theories concerned with the determination of attributions for performance in achievement settings. Students in the present study were egotistical in their attributions for three examination scores. They attributed A and B scores to ability and effort, and C, D,

and F performance to test difficulty and bad luck. However, attributions were also influenced by less motivated concerns. The path analysis indicated that the most important factor in determining expectations for Tests 2 and 3 was perceived amount of study. Given this clear basis of expectancy, the students' subsequent attributions to effort were influenced by their expectations in a manner consistent with the expectancy confirmation approach outlined by Miller and Ross (1975). Students whose expectations were confirmed on Tests 2 and 3 did make more attribution to effort, the basis of their expectations, than did students who received unexpected scores.

The results of this study highlight the important role of effort in the attribution process. While a number of previous studies have shown that attributions are affected by outcomes and expectancy confirmation (e.g., Frieze & Weiner, 1971; McMahon, 1973), the present study shows that over a series of trials, effort emerges as the single most important attribution factor. On Tests 2 and 3 effort attributions were influenced by both motivational and nonmotivational attribution processes. Effort is distinguished from the other attribution factors by the fact that it alone is under the actor's control. It may be easier for the actor to perceive the covariance between effort and outcome than to perceive the relationship between outcome and the other attribution factors (Kelley, 1967). For instance, an actor may attempt to assess the difficulty of the test while he/she is taking it, but an accurate assessment of its difficulty is probably dependent on social comparison information provided by subsequent informal discussion and feedback on class performance.

Ability and task difficulty attributions, in contrast to effort ascriptions, were relatively uninfluenced by the confirmation factor. Concern with self-protection and enhancement were the most important determinants of ability and task attributions in the present study. The path analysis suggested that unlike effort, neither ability nor task difficulty judgments were important in the formation of expectancies. According to our interpretation of the expectancy-confirmation model, lack of a direct relation between the expected effect of a factor and the expected level of performance makes it impossible for that model to make meaningful predictions of posttest attributions. This is because achieving or not achieving the score one expects has no clear implications for attributions to a factor unrelated to the production of the expectancy.

An exception to the last statement seems warranted only in the case of the luck factor. Attributions to luck, like those to effort, were generally influenced by both egotism and expectancy confirmation. But, unlike effort, luck was stressed as a causal factor by students whose expectancies were disconfirmed rather than those whose expectancies were confirmed. In further contrast to effort, the effect of confirmation on luck attributions did not depend upon whether luck was (as for Test 1) or was not (as for Tests 2 and 3) a basis for expectancy. This is because luck bears a more direct relation to the confirmation factor than do the other three factors. Estimates of luck's role are in a sense equivalent to judgments of surprise and hence should be greatest given disconfirmation of expectancy.

The results for the internal minus external composite showed that on all three tests successful students stressed internal factors to explain their performance and less successful students used external causes. For Tests 2 and 3, in addition to the egotism effect, it was shown that disconfirmed expectancies were associated with external attributions. In the present context, the internal–external composite might also be seen as a stable–unstable index. In Weiner's scheme, ability and task difficulty are regarded as stable factors and effort and luck as unstable factors. It is clear, however, that in a university examination setting test difficulty may vary throughout a semester. Additionally, we have demonstrated that effort formed the strongest basis of expectancy for Tests 2 and 3 and that effort attributions for these tests were consistent with the idea that judgments of one's amount of prior study remain stable across time. It therefore seems reasonable to interpret the emphasis on external factors by disconfirmation subjects on Tests 2 and 3 as an emphasis on unstable factors (see Frieze & Weiner, 1971).

A third and perhaps more parsimonious way to conceptualize these results is to view the composite as a comparison between attributions to factors that were important in forming expectancies versus those that were not. Given disconfirmation of Tests 2 and 3 expectancies, task difficulty and luck, factors unrelated to Tests 2 and 3 expectancies are emphasized relative to effort and ability.

Deciding upon a way to conceptualize these results depends upon the particular expectancy attribution theory one adopts. Some theorists maintain that the stability of attribution factors is the dimension most relevant for explaining the effects of confirmation and disconfirmation on causal attributions (Frieze & Weiner, 1971; McMahon, 1973; Valle & Frieze, 1976). Others stress the importance of the internal–external dimension (Feather, 1969; Miller & Ross, 1975). Still others have deemphasized the role of expectancies and have stressed the motive to make self-serving attributions regardless of the degree of expectancy confirmation (Bradley, 1978; Stephan et al., 1979). The present study suggests that closer examination of the antecedents of expectancies may be a useful way to disentangle, compare, and reintegrate these competing hypotheses.

Emergencies: What Are They and Do They Influence Bystanders to Intervene?

R. Lance Shotland and Ted L. Huston
Pennsylvania State University

Social psychological research on helping has, in part, been concerned with the intervention of bystanders into emergencies. Pertinent empirical literature does not seem to be available on what factors bystanders use to define an emergency nor the effect of such a decision on the rate of helping. A series of four studies was conducted to answer these questions. We found that (a) Emergencies are a subclass of problem situation that usually result from accidents; (b) there is a high degree of agreement concerning what problem situations are definitely an emergency; (c) emergency situations are differentiated from other problem situations by threat of harm or actual harm worsening with time, unavailability of an easy solution to the problem, and necessity of obtaining outside help to solve the problem; (d) disagreement on whether a problem situation is an emergency or not results from differing perceptions of the degree to which threat of harm or actual harm worsens with time; (e) bystanders are more likely to help in emergency than in nonemergency problem situations. The results were interpreted as indicating that the need of the victim is a salient feature used by bystanders in determining whether or not to help.

Social psychological research on helping has, in part, been concerned with the intervention of bystanders into emergencies. Surprisingly, the question of whether onlookers are more apt to help in emergencies than in nonemergencies has not been investigated, nor does there seem to be any firm theoretical basis for predicting the effect of whether or not a given situation is seen as an emergency on the rate of helping. Moreover, no evidence is available concerning the considerations bystanders use in labeling a situation as an emergency. These are the problems we wish to investigate.

This research was supported by a grant from the Central Fund for Research, College of Liberal Arts, Pennsylvania State University. We thank Steven Marks, Carolyn Edwards, and Mark Peterson for their work on various phases of the project. We also thank Jerald Barnett, Craig Bowman, Kenneth Falkenbach, Gary Foley, Christine Pogue, Alice Pope, Adrienne Ratella, and Lisa Tate for serving as confederates in Study 4.

Requests for reprints should be sent to R. Lance Shotland, Department of Psychology, Pennsylvania State University, University Park, Pennsylvania 16802.

Latané and Darley (1970), in their monograph on the unresponsive bystander, come to an equivocal position on whether a person is more or less likely to respond to an emergency situation. In laying out the reasons why bystanders may fail to help in emergencies, these writers make the following observation about emergencies: "The picture is a grim one. Faced with a situation in which he (the bystander) can gain no benefit, unable to rely on past experience, on the experience of others, or on forethought and planning, denied the opportunity to carefully consider his course of action, the bystander to an emergency is in an unenviable position. It is perhaps surprising that anyone should intervene at all" (p. 31).

Latané and Darley, in proposing their decision-making model, however, suggest that perceiving an event as an emergency is a critical determinant of whether a bystander will provide help. "If an individual is to intervene in an emergency," according to Latané and Darley (1970), "he must make not just one, but a *series* of decisions. Only one particular set of choices will lead him to

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3710-1822$00.75

take action in the situation" (p. 31). In order to intervene the onlooker must (a) notice that something is happening, (b) *interpret the event as an emergency,* (c) assume responsibility for taking action, (d) decide on the appropriate form of assistance, and (e) decide how to implement the assistance.

Piliavin, Piliavin, and Rodin (1975) take a somewhat different stance concerning the impact of emergencies on helping. According to their model, emergencies produce arousal that becomes more unpleasant as it increases. In order to reduce the unpleasant arousal, bystanders take action, the form of which depends on the line of action they perceive to be most likely to reduce their arousal quickly and effectively. Emergencies ought to intensify the actions of bystanders, but whether the onlookers run toward or away from the scene is predictable from elements in the situation other than its emergency character.

Since we are interested in determining whether emergencies stimulate helping, our first task was to identify such events and to differentiate them from other situations where help is not a matter of urgency or necessity. The emergency intervention literature has confronted onlookers with a variety of incidents, including a collapsed subways rider (Piliavin, Rodin, & Piliavin, 1969), a physical assault (Shotland & Straw, 1976), and a victim of stomach cramps (Staub, 1974). No systematic attempt has been mounted to identify the range of events perceived to be of an emergency nature.

This article reports data from four studies. The first three studies were concerned with identifying emergencies and defining their properties. The fourth study examined whether the emergency character of an event influences helping.

Study 1

The first study had two phases. In the first phase (Part A) participants were asked to identify the kinds of events that come to mind when they think of an emergency. The events identified by these respondents, as well as a sample of the kinds of events simulated by researchers studying bystander intervention, were rated as to their degree of emergency by a new set of respondents during the second phase (Part B) of the study.

Part A

Method

Subjects. The subjects were 39 men and 16 women enrolled in a social psychology course, winter term 1976, at The Pennsylvania State University.

Procedure. Subjects were asked to list events they considered an emergency that they had witnessed, imagined, or knew about. The term *emergency* was left undefined, given our interest in determining the subject's own definition.

Results

In order of frequency, the following events were identified: auto accident, fire, heart attack, drowning, flood, poisoning, airplane crash, hurricane/tornado, earthquake, rape, and war. The events can be classified into the following categories, listed in order of the number of events identified: (a) accidents; (b) illness, disease, and death due to natural causes; (c) natural disasters; (d) acts of violence and crime; (e) psychological and emotional problems (e.g., attempted suicide, nervous breakdown); (f) political problems and crises (e.g., overpopulation, oil shortage); (g) everyday problems and crises (e.g., late for an appointment, studying all night for an exam, and (h) miscellaneous (e.g., electrical power failure, financial emergency).

Part B

Method

The emergency situations generated by the subjects in Part A were augmented by a list of emergencies simulated in previous research (Huston & Korte, 1976), as well as by situations generated by the investigators.

Subjects. The subjects were 69 females and 21 males enrolled in a social psychology course, spring term 1976, at the Pennsylvania State University.

Procedure. The final pool of items consisted of 96 descriptions of events. Half of the items were put into Form A, the other half into Form B. This was done to prevent respondents from becoming fatigued. Participants rated each event in terms of whether it is an emergency on the following 5-point scale: (1) definitely an emergency, (2) probably an

Table 1
Classification of Events

Event	*M*	*SD*	Category
Definite emergency			
Cut artery, profuse bleeding	1.00	.00	Accident
House ablaze, people screaming for help	1.00	.00	Accident
Child poisoned	1.00	.00	Accident
Child swallowed razor blade	1.00	.00	Accident
Person in shock, lying on ground	1.07	.25	Accident
Heart attack	1.02	.15	Illness, disease
Airplane crash, some passengers still alive	1.02	.15	Accident
Rape in progress	1.09	.36	Act of violence
Car accident, driver motionless on ground	1.09	.29	Accident
Drug overdose	1.09	.46	Accident
Not sure[a]			
Terminal cancer, 3 mos. to live	2.60	1.35	Illness, disease
Lost person in woods shouting for help	2.64	1.03	Miscellaneous
Car broken down on side of road	2.72	.98	Everyday problem
Emergency landing by airplane, passengers shaken but unhurt	2.78	1.08	Accident
Burning leaves, no one attending, windy day	2.81	.95	Accident
Rock stars in danger of being trampled by fans	2.84	1.18	Miscellaneous
Mildly intoxicated friend wants to drive home	2.84	1.18	Everyday problem
Blackout in neighborhood	2.98	1.03	Miscellaneous
Man on first date with woman he likes, no money	3.07	1.08	Everyday problem
Friend states he is miserable and depressed	3.18	.92	Psychological and emotional problems
Probably not an emergency			
Car door chips other car's paint	3.75	1.06	Everyday problem
Telethon wants to get $20 million for muscular dystrophy	3.75	1.17	Miscellaneous
Car parked by fire hydrant	3.98	.98	Everyday problem
Scraped knee	4.05	.84	Everyday problem
Tramp panhandling	4.05	.99	Everyday problem
Tray of hors d'oeuvres drops at party	4.09	.91	Everyday problem
Child holds breath in protest	4.18	.97	Everyday problem
Person loses dime in pay phone	4.23	.94	Everyday problem
Cat is stuck in a tree	4.23	.73	Everyday problem
Someone has cigar, no match	4.87	.54	Everyday problem

[a] *M*s closest to 3.

emergency, (3) not sure, (4) probably not an emergency, (5) definitely not an emergency.

Results

The most striking finding is that our participants agree considerably concerning what events are emergencies. In fact, four items were seen as definitely an emergency by *all* respondents; several other events were seen as definite emergencies by *all but a few* of the respondents. As can be seen in Table 1, the events seen as emergencies were primarily accidents. At the other end, problems seen as probably not an emergency were categorized, for the most part, as everyday problems. Situations that elicited uncertainty concerning their emergency nature fit a number of categories, including everyday problems, psychological and emotional problems, and other miscellaneous occurrences. From Table 1 it is apparent that emergencies appear to be a special class of problem situations.

As noted earlier, a sampling of events simulated in the laboratory in previous research was rated by our respondents in terms of their degree of emergency. These events tended to be rated as probably an emergency. Representative events are as follows: a collapsed subway rider ($M = 1.50$; $SD = .73$), a person lying on the floor having fallen from a ladder ($M = 1.61$; $SD = .64$), an individual suffering from an asthmatic attack ($M = 2.00$; $SD = 1.10$), a person groaning and lying in a doorway ($M = 2.02$; $SD = .77$), and an individual complaining of severe stomach cramps ($M = 2.38$; $SD = .86$).

Study 2

The next step is to identify the defining qualities of emergencies that distinguish them from other problem situations. Latané and Darley (1970) have drawn a portrait of emergencies. We shall draw heavily from their observations, elaborating them in terms of insights gleaned from Table 1. First, as can be seen in Table 1, events seen as definite emergencies *all happen suddenly and unexpectedly*. Victims and bystanders alike find themselves unprepared. Eight of the 10 events most consistently seen as definite emergencies were accidents; the remaining 2—heart attack and rape—also catch their victims by surprise. The fact that something happens without warning, however, does not necessarily indicate an emergency. Dropping a tray of hors d'oeuvres at a party may be embarrassing, but according to our respondents, it is probably not an emergency.

A second important feature of emergencies is that they involve *threat of harm* or actual harm to the victim. Events seen by our respondents as definite emergencies all threaten the life of the victim. A cut artery, poisoning, and drug overdose are unambiguous with regard to their life-threatening potential. In each case, in addition, *immediate, urgent action is required* if the victim is to be saved. Too much loss of blood or the failure to find an antidote quickly to counteract the poison or the drug would be fatal. In contrast, events that were seen as nonemergency problems or that our respondents were unsure how to classify pose little or no threat of harm to the victim. A child holding his breadth in protest may put a scare into his parents, but our respondents did not think of it as much of an emergency. Similarly, a person who scrapes a knee or loses a dime in a pay phone may feel distressed, but others are unlikely to see this situation as an emergency.

Another important feature of an emergency is that *outside help is necessary*. Without the intervention of an onlooker, the victim is unable to keep the situation from worsening. A helpless victim is characteristic of all situations classified as definite emergencies in Table 1. The fact that a victim is helpless, however, does not necessarily indicate that an emergency is at hand. Victims of terminal cancer are helpless, but our respondents were uncertain whether to classify their circumstances as an emergency. This suggests, perhaps, that in order for an event to be seen as an emergency, *it must be possible for onlookers to do something* to help the victim.

The above analysis suggests that emergencies involve several essential features:

1. They occur suddenly and unexpectedly.
2. They involve threat of harm or actual harm to the *victim*.
3. The threat increases with time.
4. The victim is helpless.
5. Potentially effective intervention must be possible.

According to the data in Study 1, it appears that events that involve one of the above features but not others are unlikely to be seen as definite emergencies. We expect to see "threat of harm" (2) and "threat of harm increasing with time" (3) to be moderately to highly correlated. A moderate correlation is predicted between "something can be done to correct the situation" (4) and "outside help is necessary" (5).

Method

Brief scales comprised of both positively and negatively worded Likert-type items were constructed to measure each of the factors that were hypothesized to define an event as an emergency. The scale designed to measure the degree to which an event occurred suddenly and unexpectedly consists of 10 items such as "the incident occurred without warning" and "the situation could have been anticipated." Guttman's lamda-3 index of reliability was measured

as .88 and .80 on two data sets using different clusters of situations. The scale measuring threat of harm or actual harm consisted of 13 items yielding a Guttman lambda-3 index of reliability of .83 and .88. A representative item from this scale is "individuals or property involved will only benefit from this situation." The scale indexing threat of harm or actual harm increasing with time had reliabilities of .79 and .79 with a total of 8 items. An example from this scale is "the probability of threat or harm to the person or property increases with time." The scale designed to tap whether something can be done to correct the situation consisted of 9 items yielding a Guttman lambda-3 of .83 and .79. An example of an item from this scale is: "help will be effective in solving the problem." The scale designed to ascertain whether outside help is necessary contained 10 items and had Guttman reliabilities of .75 and .79. "Others are needed to help change the situation" is an item taken from this scale.

The items from the five scales were randomized along with an additional 5-point Likert-type item designed to measure subjects' perceptions of a problem situation as an emergency. The anchor points of the latter measure were (1) definitely an emergency and (5) definitely not an emergency, with (3) being not sure.

To increase the generalizability of the results, we decided to investigate the defining features of three problem situations. Two situations that were rated as "probably an emergency" by subjects in Study 1 were randomly chosen. We used situations rated as "probably an emergency" for two reasons. First, situations rated as "definitely an emergency" had either no or very little variance. Second, as we pointed out previously, this is the category that most of the situations used by previous researchers investigating emergency intervention phenomena had used in their research. The first emergency situation was "you see a driver weaving from one side of the road to the other. He is apparently drunk" ($M = 2.07$; $SD = 1.04$). The second situation was: "you see the classmate next to you have an asthmatic attack" ($M = 2.00$, $SD = 1.10$). We also wished to investigate crimes as emergencies, as one might expect that crimes might be emergencies with different defining characteristics. However, the crimes on our list were all rated as "definitely an emergency" and had little or no variance. So a crime was chosen from Rossi, Waite, Bose, and Berk's (1974) list of crimes ordered in terms of seriousness. We chose a crime that was not seen as extremely serious. This problem situation was: "you see a young man grab the purse from an elderly woman and run away."

Subjects. The subjects were 279 undergraduates from an introductory psychology course at The Pennsylvania State University during the spring term of 1977. Subjects were randomly assigned a given emergency situation: 57 males and 43 females were assigned to the drunk driver situation; 50 males and 38 females were assigned to rate the asthmatic attack; and 45 males and 45 females, plus one respondent whose sex was not ascertained, rated the purse-snatching incident.

Procedure. The subjects were given the questionnaire described above. The questionnaire contained a front page that listed one of the three problem situations and provided instructions to the subject to rate the situation on each of the items listed on the following pages. A sample of the Likert scale format was included on the front page of the questionnaire as well as on each succeeding page.

Results

As Table 2 illustrates, if we view across all three emergency situations and look at the half of the matrix corrected for attenuation, the scale measuring the degree to which an event is seen as sudden and unexpected bears little relationship to the other scales. The remaining four scales are moderately related with one another and share between 15.2% of the variance (threats of harm with outside help necessary) and 38.4% of the variance

Table 2
Attenuated and Unattenuated Pearson Correlation Matrix Indicating the Interrelationships Between the Variables Hypothesized to be Components of an Emergency Across the Three Emergency Situations

Variable	1	2	3	4	5	6
1. Sudden and unexpected	—	−.19	−.07	.08	.14	−.06
2. Threat of harm	−.23	—	.35	.30	.31	.24
3. Harm increases with time	−.09	.43	—	.41	.48	.51
4. Something can be done	.10	.40	.56	—	.36	.25
5. Outside help necessary	.17	.39	.62	.50	—	.30
6. Emergency	−.06	.26	.57	.30	.35	—

Note. Below the diagonal are correlations corrected for reliability, above it are the attenuated correlations. To test for significance use the attenuated matrix. Correlations equal to or above .14 are significant at the .05 level.

Table 3
Regression Analyses of the Variables That Lead to a Decision That a Problem Situation Is an Emergency (Corrected for Attenuation)

Variable in order of insertion into regression equation	Multiple R	R^2	β	F
Problem Situation 1: Asthmatic attack				
Harm increases with time	.613	.376	1.060	41.17*
Something can be done	.677	.458	−.568	13.22*
Sudden and unexpected	.695	.484	−.158	3.54
Threat of harm	.704	.496	.140	2.13
Outside help necessary	.705	.496	−.040	.11
Problem Situation 2: Drunk driver				
Harm increases with time	.717	.514	.984	38.75*
Outside help necessary	.743	.552	−.283	4.94
Sudden and unexpected	.756	.572	.141	3.44
Something can be done	.758	.574	.093	.85
Threat of harm	.759	.576	−.080	.34
Problem Situation 3: Purse snatching				
Harm increases with time	.360	.130	.344	7.24*
Something can be done	.369	.136	.148	1.25
Threat of harm	.382	.146	−.150	1.20
Sudden and unexpected	.392	.154	−.103	1.00
Outside help necessary	.395	.156	.070	.25

* $p < .01$.

(harm increases with time with outside help necessary).

Regression was employed to determine the impact of various perceptual elements in our subjects' definitions of events as emergencies. In Table 3, R and R^2 are ordered as they were produced by a forward stepwise regression. The beta weights and F ratios are the product of the summary analysis in which the final regression equation, which had all the variables entered, was used. Thus, the F ratios and beta weights reflect the contributions of each of the variables by holding constant all of the other variables. Since differences in the reliabilities of the scales can cause disparities due to measurement error rather than to the variables themselves, we decided to conduct the analyses on matrices corrected for attenuation due to imperfect reliability. However, one must be cautious in interpreting tests of significance based upon data corrected for attenuation, in that the test statistic, as well as other coefficients, is inflated as a result of increased sampling error (Cohen & Cohen, 1975). Therefore, we have set alpha at the .01 level, and we will report differences in conclusions regarding each study that are reached by doing the regression analysis on attenuated data using the standard confidence interval. Since no sex differences were found for either the emergency question or with regard to any of the scales, the samples were combined for the regression analysis. The results are shown in Table 3.

The asthmatic attack was generally seen as probably an emergency ($M = 2.10$, $SD = .87$). There were two statistically significant predictors of the degree to which the asthmatic attack was viewed as an emergency. As shown in Table 3, the most important predictor was harm increasing with time, which was entered first and accounted for approximately 38% of the variance. Whether the incident was seen as one in which something could be done to help the victim was the second statistically significant variable and accounted for another 6.4% of the variance.

Table 4
Regression Analysis Across 96 Problem Situations of the Variables That Lead to a Decision That a Problem Situation Is an Emergency (Corrected for Attenuation)

Variable in order of insertion into regression equation	Multiple R	R^2	β	F
Harm increases with time	.856	.733	.654	11.78*
Something can be done	.908	.824	−.255	13.54*
Outside help is necessary	.916	.838	.222	7.34*
Threat of harm	.917	.840	.130	.84
Sudden and unexpected	.917	.842	.039	.80

Note. Reliabilities were calculated across emergencies rather than subjects and these reliabilities were used to correct for attenuation.
* $p < .01$.

The drunk driver situation was again seen by most of our respondents as "probably an emergency" ($M = 2.05$, $SD = .97$). Again, harm increasing with time was entered into the equation first. It accounted for approximately 51.4% of the variance. No other scale was a significant predictor of perceiving the event as an emergency.

The purse-snatching situation was rated as probably an emergency by most of our subjects ($M = 1.96$, $SD = .91$). As Table 3 shows, harm increasing with time was the only scale that was significantly tied to the perception of the event as an emergency accounting for 13% of the variance in the emergency ratings.

Discussion

Only one of the variables, threat of harm increasing with time, was a significant predictor of perceiving the event as an emergency across all three situations. No other variable was significant across any two of the situations. The same conclusion is reached if the attenuated matrix is used. We find these results surprising. Perhaps the discrepancy between our expectations and the results reflects differences in our conceptualization and our test of the model. In formulating the model we were attempting to identify the critical dimensions that differentiate emergency situations from other problem situations. The test provided in this study asked the question: What are the considerations that cause different people to see the same situation differently? This is an important question, particularly if individual differences in perceiving an event as an emergency relate to the likelihood that onlookers respond. We would now like to focus our attention on answering the question: What features do people use to differentiate emergency situations from other nonemergency problems?

Study 3

Method

The same questionnaire used in Study 2 was used in Study 3. Instead of selecting 3 problem situations, all of which were about equal in the degrees to which they were likely to be seen as an emergency, all 96 problem situations used in Study 1 were again employed. Each situation was rated by a minimum of four subjects ($M = 5.44$), who were randomly assigned to the emergency situations. The responses of subjects who rated a given emergency were averaged, thereby producing average scale scores and an average rating of the situation as an emergency. The correlational analysis, then, is across 96 problem situations rather than subjects. The variance generated with this procedure is basically due to differences in situations rather than to individual differences in the perceptions of the subjects.

Subjects. The subjects were 522 male and female undergraduates at The Pennsylvania State University. The students participated during the fall term of 1977 and winter term of 1978 and earned supplemental credit for their introductory psychology course.

Results

The regression procedures used in Study 2 were also employed in Study 3. As Table 4 indicates, and as found in Study 2, "harm

increases with time" was an important predictor accounting for 73.3% of the variance. The second statistically significant variable was "something can be done," which accounted for another 9.1% of the variance and yielded a negative beta weight. The last statistically significant variable was "outside help is necessary," accounting for another 1.4% of the variance.

The zero-order (Pearson) correlation matrix illustrating the interrelationships among the variables shown in Table 5 provides additional information. This correlation matrix, although similar to the one presented in Table 2 in some respects, differs in others.

Again, it appears that the sudden and unexpected variable bears a small relationship to the other variables. In general, however, the relationships among the other variables are much higher. Of particular note is the corrected correlation between "harm increases with time" and "threat of harm." The correlation between those two scales was .89, indicating that "threat of harm" and "harm increases with time" are basically the same variable. The correlation between "harm increases with time" and "outside help is necessary" ($r = .80$) indicates that these two variables also show a great deal of common variance.

The negative beta weight of "something can be done" along with its zero-order correlation of .05 with the emergency question and its zero-order correlation of .38 with "harm increases with time" and .22 with "outside help is necessary" indicates that "something can be done" is working as a suppressor variable in the multiple regression equation (see Nunally, 1967). This is consistent with the negative beta weight associated with the "something can be done" variable found in the asthmatic attack situation in Study 2. The regression analysis based upon the attenuated correlation matrix leads to the same general conclusion. In this analysis, threat of harm proved to be a significant predictor of perceiving events as emergencies.

Table 5
Attenuated and Unattenuated Correlation Matrix Indicating the Interrelationships Between the Variables Hypothesized to be Components of an Emergency Across the 96 Emergency Situations

Variable	1	2	3	4	5	6
1. Sudden and unexpected	—	.16	.13	.04	.20	.21
2. Threat of harm	.19	—	.74	.03	.53	.78
3. Harm increases with time	.15	.89	—	.30	.65	.78
4. Something can be done	−.05	.04	.38	—	.17	.04
5. Outside help necessary	.24	.65	.80	.22	—	.70
6. Emergency	.23	.85	.86	.05	.78	—

Note. To test for significance use the attenuated matrix (i.e., the correlations above the diagonal). Correlations equal to or above .17 are significant at the .10 level, correlations equal to or above .20 are significant at the .05 level.

Discussion

It appears that a major determinant of whether or not a problem situation is seen as an emergency is the presence of harm or threat of harm. If there is a sufficient amount of harm, then almost by definition it becomes worse with time. In addition, if the amount of harm is sufficiently grave, then outside help is necessary. The negative beta weight associated with "something can be done" indicates that if there is an easy solution to the problem, it is less likely to be viewed as an emergency.

For example, Table 1 illustrated that a scraped knee was generally not seen as an emergency ($M = 4.05$). Harm is minimal, providing that infection doesn't set in. It does not get worse with time, and no outside help is required in that the victim generally can take care of the problem of cleaning the abrasion and putting a Band-Aid on it. On the other hand, Table 1 indicates that all of our subjects saw a cut artery with profuse bleeding as a definite emergency ($M = 1.00$). In this incident, there is a greater degree of harm than with a scraped knee—at the least the cut is deeper. The situation is worsening with time, in that if nothing is done the person may well bleed to death. With this type of injury an outside source of help with medical expertise is usually required to solve the

problem directly. One might expect that a person that knows that "something can be done" and precisely what to do, for example, a doctor with a cut artery and proper equipment, may regard the incident as much less of an emergency.

Of the three considerations used by respondents in Study 3 to discriminate between emergency situations and nonemergency problems, only one differentiated respondents in Study 2 in terms of the degree to which they saw events as emergencies. This factor was the degree to which they saw harm to the victim increasing with time.

Study 4

Our original intention was to unravel the concept of an emergency and, once we understood its important features, to design a factorial experiment assessing the relative importance of the elements in accounting for helping. The findings of the third study, however, clearly indicate that the defining ingredients of an emergency are tightly intertwined (see Table 5), thereby making it impossible to separate them factorially. Study 3 demonstrated that the perceptions of threat of harm or actual harm, harm increasing with time, and outside help as necessary were highly intercorrelated. Furthermore, the perception that "something can be done" acted as a suppressor variable, meaning that taken alone it did not correlate with people's ratings of events as emergencies. Although we now know what people mean by an emergency, we could not experimentally isolate its component parts. The key question remains, however, as to how people behave in emergency versus nonemergency situations, and that is what the next study was designed to answer.

Method

Given the high intercorrelations between two of the three factors used to predict an emergency and the indirect effect of the third factor, it did not seem reasonable to use a factorial design to try to decipher the relative importance of the three factors in providing help. We decided simply to examine emergencies versus nonemergencies. The major difficulty is to construct problem situations of an emergency and nonemergency nature that require the same kinds of help, so that the two types of situations are comparable. We decided that the most reasonable procedure was for the persons who needed help always to ask for a ride to a given location following their explanations of why the ride was necessary.

The setting was the student parking lot at The Pennsylvania State University. Four male and four female undergraduate and graduate students served as the help solicitors. The solicitors varied in age (from 19 to 30 years) and in physical characteristics, although none was extreme as to size, weight, or attractiveness. Males varied on length of hair and amount of facial hair. The solicitors were stationed at various points in a parking lot capable of holding 1,340 automobiles. When a subject approached an automobile in the solicitor's area, or when a car was being parked in the solicitor's area, the solicitor would approach the potential subject and explain his or her predicament following a script and keeping to a standardized, moderate level of affect. The solicitor would then ask for a ride to his or her home in a small town approximately 5 miles away. Seven emergency and nonemergency situations were used. Some examples of emergency and nonemergency situations are:

1. "Excuse me. I need some help. I'm a diabetic and I forgot to take my insulin this morning. I'm long overdue. Can you give me a ride home to Boalsburg?" (emergency).

2. "Excuse me. I need some help. I forgot to take my allergy medicine this morning and it's starting to bother me. Can you give me a ride home to Boalsburg?" (nonemergency).

3. "Excuse me. I need some help. My roommate called and she took an overdose of sleeping pills. Can you give me a ride home to Boalsburg?" (emergency).

4. "Excuse me. I need some help. My roommate called and sounded very depressed. Can you give me a ride home to Boalsburg?" (nonemergency).

Once the subject's response was ascertained he or she was immediately debriefed. A response was counted as helping if the subject offered to take the solicitor to the appointed destination.

Subjects. The subjects were 286 male and female students (208 males and 78 females) who were alone and were either entering or exiting from their automobile in a student parking lot on The Pennsylvania State University campus during spring term of 1978.

Hypotheses

The key hypothesis concerns whether people are more inclined to help in emergencies or in nonemergencies. As we indicated in the introduction to the paper, there is no theoretical basis for making a prediction. Nonetheless, we expect people to help more frequently in emergencies compared to nonemergencies because bystanders should perceive a greater

need for their assistance. In order to generalize, we employed a number of different emergency and nonemergency situations and used both male and female solicitors. Given that the subjects were of both sexes and were either arriving at or leaving the lot, we recorded this information as well. Since we collected this information, the following additional hypotheses were formulated.

1. Based upon previous research (e.g., Borofsky, Stollak, & Messé, 1971; Piliavin & Piliavin, 1972), we hypothesized that males will help more than females.

2. Latané and Dabbs' (1975) research suggests that females should receive more help than males.

3. We expect subjects who are arriving at the parking lot to be less helpful than subjects who are leaving the lot. Commuters who are arriving should be, on average, going to class, whereas those who are leaving should have greater time flexibility. Darley and Batson (1973) found that subjects in a hurry help less frequently than subjects with more time.

Results

Manipulation check. The first step is to determine whether our emergency events are seen as emergencies in comparison to our nonemergency events. To accomplish this, 168 subjects rated the situations. Each of our 14 situations was described to separate groups of 6 males and 6 females earning extra credit in an introductory psychology class. They were asked to imagine themselves walking near their car in a parking lot and having a person approach them who then made one of the 14 statements used in the study. The subjects were then asked to fill out a short questionnaire concerning the situation. The emergency question used in each of the earlier studies was again used here. The results showed that our emergency situations were indeed seen as emergencies ($M = 1.94$) in comparison to our nonemergency situations ($M = 3.14$), $F(1, 164) = 74.35$, $p < .001$. The degree to which an event was seen as an emergency was strongly correlated (.75) with judgments concerning the severity of the situation. There was no difference between males ($M = 2.64$) and females ($M = 2.44$), $F(1, 164) = 2.11$, *ns*, nor were differences found due to the specific incidents or to interactions between and among the nature of the event, the sex of the respondent, and the specific events.

Tests of hypotheses. The data from the factorial study were analyzed by means of Goodman's techniques for the assessment of interaction effects in multivariate contingency tables (Bishop, Fienberg, & Holland, 1975). Using analysis of variance terminology, the model of the four-way interaction was significant, $\chi^2(1) = 8.04$, $p < .005$. In nonemergency situations when female subjects were arriving and a male solicitor asked for a ride, *none* of the 12 subjects in that cell helped in comparison to the average helping rate of 55% across all cells. This is precisely the cell one would predict the lowest rate of help from. The models of the three-way and two-way interactions were not significant. In fact, if one lumps all four-, three-, and two-way interactions together and drops them from the model, leaving main effects, one loses a nonsignificant chi-square, $\chi^2(11) = 15.47$. Since the four variables only interact if all the variables are present and do not interact in any form with a subset of these variables, it is not useful to consider this model except in the unlikely possibility that another researcher is going to combine those four variables.

Three of the main effects were also statistically significant. More help was produced in emergency conditions (64%) than in nonemergency conditions (45%), $\chi^2(1) = 11.17$, $p < .001$. Female solicitors received more help (64%) than male solicitors (47%), $\chi^2(1) = 9.04$, $p < .01$. Males helped (61%) more than females (40%), $\chi^2(1) = 11.48$, $p < .01$. In addition, subjects who were arriving on campus (50%) were marginally less likely to help than subjects who were leaving (63%), $\chi^2(1) = 3.84$, $p < .10$. If we drop the data from the cell that caused the four-way interaction where no one helped, and use a chi-square procedure to recalculate the main effects to determine if the main effect is independent of the interaction, we find that the main effect due to the presence or absence of an emer-

gency is independent of the four-way interaction, $\chi^2(1) = 5.76$, $p < .02$. The sex of the solicitor is marginally significant, $\chi^2(1) = 3.74$, $p < .10$, as is the sex of the subject, $\chi^2(1) = 3.76$, $p < .10$. The main effect due to whether the subject is coming or going, however, is dependent on the interaction, $\chi^2(1) = 2.37$, *ns*.

Discussion

The data from Study 4, when considered together with the findings of Study 3, indicate that a prime concern motivating potential helpers is the degree to which the victim is in need of help. From Study 3 it was determined that our subjects defined an emergency primarily in terms of the presence of a sufficient amount of harm or threat of harm such that the situation was both worsening with time and that outside help was necessary.

The results of Study 4 indicate that people are more inclined to help in an emergency as compared to nonemergency situation. This research is not the only line of research that indicates that the bystander's perceptions of the need of the victim are an important determinant of whether or not help is offered. Weiss, Boyer, Lombardo, and Stitch (1973) found that the more pain a person is in, the more rapidly people will provide help. In another study, Staub and Baer (1974) investigated the severity of an incident by having a confederate feign either a heart attack or a twisted knee. Although the results were not entirely consistent, they concluded that the greater the severity, the more the helping. West and Brown (1975) used blood as a sign of severity and found more help when blood was used; in contrast, Piliavin and Piliavin (1972) found less help with the use of blood. A recent study by Clark (1975) found that the less a person is able to help himself, the more inclined people are to provide help. His data showed that a man on crutches who had dropped a book was much more likely to be helped than a man walking normally. Finally, Shotland and Johnson (1978) varied the severity of a fall and found that onlookers were more apt to help the victim after a bad fall than after a mild one. As a group, these studies document the importance of severity of need as a determinant of bystander intervention.

General Discussion

The data reported in the four studies bears on both Latané and Darley's (1970) decision-making model and the arousal reduction model of bystander intervention set forth by the Piliavins and their colleagues (Piliavin et al., 1969; Piliavin et al., 1975; Walster & Piliavin, 1972; Piliavin & Piliavin, Note 1). It will be recalled that Latané and Darley (1970) suggested that the decision to intervene is based on a series of decisions: (a) notice that something is happening, (b) interpret the event as an emergency, (c) assume responsibility for taking action, (d) decide on the appropriate form of assistance, and (e) decide how to implement the assistance. Our data suggest that the decisions are not conceptually distinct. Latané and Darley's (1970) second decision in the series—that an event is an emergency—is affected by the conclusions onlookers come to regarding the third and fourth decisions—that is, the degree to which onlookers believe they are in a position to help and take responsibility for providing help in one form or another. If the victim is able to extricate himself without the aid of a bystander, or if no form of assistance is likely to help correct the situation, then there is no action to take and therefore no reason to take responsibility for the situation. The interpretation that a problem situation is an emergency is not only based on harm or threat of harm to the victim increasing with time but also on the degree to which outside help is both necessary and feasible. Thus, the decision that an event is an emergency is colored by the judgments onlookers make concerning the importance and feasibility of taking action to correct the situation.

The work of the Piliavins has emphasized the idea that onlookers confronted with an emergency choose a course of action based on their assessment of the rewards and costs that they believe flow from various lines of behavior. Their research (Piliavin et al., 1969; Piliavin et al., 1975) has focused particularly

on the effects on bystander response of variations in the costs to the bystander of direct intervention. The data reported herein, when combined with the material summarized earlier, suggest that another important factor influencing the response of onlookers is their perception of the degree to which the victim is in need of help. Indeed, such a perception lies at the cornerstone of Schwartz's (1977) recent model of the decision processes that precede taking action in a distress situation. According to Schwartz (1977), the following sequential steps are involved in arriving at a decision regarding whether or not to take one or another form of action: (a) awareness of a person in a state of need, (b) perception that there are actions that could relieve the need, (c) recognition of own ability to provide relief, (d) apprehension of some responsibility to become involved, (e) activation of preexisting or situationally constructed personal norms of moral obligation, and (f) assessment of costs and evaluation of probable outcomes of taking action. Depending on the assessment of costs, onlookers are expected either to take action or not, or to reassess and redefine the situation by doing such things as denying the victim's need or by denying their own responsibility to respond. The fourth study in our series varied the potential helper's perception of the degree to which the victim was in need and assessed the degree to which the perception of need influenced the frequency of helping behavior. Models of bystander intervention have emphasized the hedonistic view of onlooker behavior and underplayed the altruistic features of the act. Although a plausible case can be made for assuming that reducing another's distress is rewarding, a strong argument can be set forth that bystander behavior can be understood more readily by focusing on objective costs to the bystander weighted against the benefits to the victim. If this is, in fact, what bystanders do, then it would appear that a model positing "limited altruism" might be more accurate than the hedonistic model.

Self-Awareness and Transgression in Children: Two Field Studies

Arthur L. Beaman and Bonnel Klentz
University of Montana

Edward Diener
University of Illinois at Urbana-Champaign

Soren Svanum
Indiana University—Purdue University at Indianapolis

Two field studies explored the relationship between self-awareness and transgressive behavior. In the first study, 363 Halloween trick-or-treaters were instructed to only take one candy. Self-awareness induced by the presence of a mirror placed behind the candy bowl decreased transgression rates for children who had been individuated by asking them their name and address, but did not affect the behavior of children left anonymous. Self-awareness influenced older but not younger children. Naturally occurring standards instituted by the behavior of the first child to approach the candy bowl in each group were shown to interact with the experimenter's verbally stated standard. The behavior of 349 subjects in the second study replicated the findings in the first study. Additionally, when no standard was stated by the experimenter, children took more candy when not self-aware than when self-aware.

The theory of objective self-awareness (Duval & Wicklund, 1972; Wicklund, 1975) proposes that a person's attention may be focused inward toward the self (self-aware) or outward toward the environment. According to the theory, when self-aware, a person is likely to focus on the standards of behavior appropriate to the setting and upon the consistency of his/her behavior with these standards. Self-aware individuals are more likely to self-regulate (Kanfer, 1970) their behaviors to be consistent with normative standards when such standards are salient. Several laboratory studies have demonstrated such effects. Diener and Wallbom (1976) found college students cheated less on an "intelligence test" if they were made self-aware by observing their reflection in a mirror and listening to their own tape-recorded voice. It has also been shown that self-awareness may either increase or decrease aggression in a laboratory situation, depending on the direction of the experimenter-produced norm (Carver, 1975; Scheier, Fenigstein, & Buss, 1974).

Transgressing a Standard

The present research extended the theory to a new population and further examined the relationship between self-awareness and self-regulation. A standard of behavior was made salient to Halloween trick-or-treaters by instructing them to take only one candy. They were then presented with an opportunity to "transgress" by taking extra candy. (It should be remembered that self-awareness theory itself is not a moralistic theory but one of consistency between behaviors and any standard of interest.) By varying the presence or absence of a mirror, it was possible to examine the effect of self-awareness on the rate of transgression (taking extra candy). The field study would reduce demands that might occur in laboratory studies and offer generalization to a noncollege population. It was hypothesized that the presence of the mirror would decrease the incidence of transgression.

We thank the many competent assistants who aided in the implementation of these two studies.

We noted, however, that the children in this research would be in costume. If the children focused on their costumes, which are aspects of the external environment, mirror presence might not elicit self-awareness. Thus half of the children were asked their names and addresses to individuate them and make their identities salient just prior to entering the room where the candy and mirror were. It was expected that the mirror might have its predicted effect only in the individuated condition.

Age

By collecting age data on the children, the present study also provided some evidence concerning the developmental course of self-awareness as it affects self-regulation. It is not known whether children, either young or old, experience self-aware states or whether these states influence their behavior. The ability to be self-aware and to focus on behavior/standards discrepancies in order to regulate behavior probably develops over a period of time. Duval and Wicklund (1972) suggested that children must learn the objectlike nature of the self before they can become self-aware. Although not speculating about the age at which this occurs, Duval and Wicklund argue that self-awareness arises as the child repeatedly encounters "situations that cause him to examine dimensions of himself . . . to build up a unified conception of himself, a conception that will constitute a comprehensive causal agent self. . ." (p. 52). It is also possible that children have not developed internalized standards at young ages. Therefore we hypothesized that the self-awareness effects would vary as a function of age, with the older children being relatively more influenced by the manipulation.

Naturally Occurring Standards

The present design also allowed an examination of the influence of self-awareness on naturally occurring modeling. The behavior of the first child to approach the candy bowl in each group might provide the subsequent children with a standard of behavior. This naturally occurring standard might support or might conflict with the admonition of the experimenter to take only one candy, depending on whether the first child did or did not transgress. The distinction between verbally stated standards and the standards expressed implicitly in the behavior of peers could prove theoretically valuable. It is possible, for example, that self-awareness may focus persons' attention differentially on one or the other standard. The present study allowed a post hoc examination of the influence of self-awareness on unstated norms as well as on those that were verbally specified.

Deindividuation Theory

A paradigm similar to the present one has been used previously (Diener, Fraser, Beaman, & Kelem, 1976; Diener, Westford, Diener, & Beaman, 1973) to investigate deindividuation theory (Zimbardo, 1970). Since only half of the trick-or-treaters in the current study were individuated (asked their name and address), the behavior of the remaining children could offer additional information on the effects of anonymity, which is a deindividuation theory input variable.

A deindividuation theory perspective would argue that transgressions increase as anonymity increases, although data on this point have been somewhat inconsistent (see Diener, 1977). This prediction is quite similar in some respects to the self-awareness theory perspective. Both imply that people are least likely to match their behavior to norms when they are not aware of themselves as individuals. Indeed, several authors (e.g., Diener, 1977) have suggested the possibility of merging self-awareness and deindividuation theories.

Because the present study included two variables traditionally considered to be antecedents of deindividuation (anonymity and group presence), predictions of deindividuation theory could also be tested. This might provide the basis for further integration of the two theories.

Experiment 1

Method

Participants and Setting

The participants were 363 children who arrived to trick-or-treat between 5:00 and 8:00 p.m. on Hal-

loween, 1976, at any of 18 selected homes. Children were used only if they were not with a parent. Thus all were old enough to be able to state their name and some description of where they lived. Furthermore, only children who came disguised by a costume, mask, or painted face were used. When too many children appeared at one time (more than 7), or if a second group of children arrived before the experimenter could leave the room, these children were not included as subjects.

The 18 homes were arranged in the same basic pattern. Inside a room near the front door was a low table approximately 5 feet (1.5 m) long. On the table was a large bowl full of wrapped, bite-sized candy bars that was replenished frequently during the evening. A large mirror was used in the self-awareness condition. The mirror rose above the table to a height of at least 5 feet (1.5 m) from the floor. The mirror was placed directly behind the table at a 90° angle such that the children would always see themselves while reaching for the candy. Within full view of the bowl was a decorative backdrop with a peephole that camouflaged an unobtrusive observer.

Procedure

A female experimenter greeted all children who came trick-or-treating, and an assistant served as the unobtrusive observer who recorded the data. Whenever a child or children arrived, the experimenter would greet the child(ren) amicably and would comment on their costumes. The experimenter then told each child, "You (or each of you) may take one of the candies. I have to go back to my work in another room." The purpose of this, as in past studies, was to make the standard of taking only one candy clearly salient. If any child had any questions about what was supposed to be done, the experimenter repeated the instructions to take one candy. She then exited and made sure she was out of sight of the children.

The observer recorded the number of children who entered the house, the number of candies taken by each child, and the estimated age and sex of each of the children. In past research and pilot studies, estimates of number of candies taken have been found to be highly reliable. With regard to age estimations, any inaccuracies would tend to obscure real differences between the age groups. If observers tend consistently to overestimate or underestimate ages, then the age data would just be shifted consistently up or down and would be less specific but would not obscure the trends present.

Since the experimenters in each house knew whether or not a mirror was present and at least the greeter knew whether or not children were individuated (see below), experimental bias was possible. However, a number of controls minimized this concern. Both mirror and no mirror conditions were run at each home, and a large number of homes and experimenters were used. Although all experimenters were carefully trained and rehearsed in the procedures, most were not on the research team involved in designing the study and hence were blind to the predictions made. Also, due to the relatively large number of conditions, systematic inaccurate recording of the data was less likely. Additionally, since the mean number of subjects per house was 26, trends in the various conditions should not have been apparent to any group of experimenters at a particular home.

Self-awareness manipulation. In this condition a large mirror was placed behind the table. Half of the homes were randomly assigned to the self-awareness condition from 5:00 to 6:30 p.m. At 6:30 p.m. mirrors were removed in these homes, whereas in the remaining homes, mirrors were placed behind the tables and the self-awareness conditions were run from 6:30 to 8:00 p.m.

Individuation manipulation. There was a concern prior to the experiment that the mirror manipulation of self-awareness might be ineffective for costumed (anonymous) children. The mirror might focus their attention on their costumes,[1] not upon themselves as individuals. Thus, it might be more difficult to make anonymous children self-aware. It was therefore considered important to shift the focus of attention from examining and appreciating one's costume to reflection upon oneself. To do this, after greeting the children and commenting on their costumes, the experimenter explicitly asked each child in the individuated condition what his or her name was and where he or she lived. The experimenter carefully repeated each child's name and address to make it salient that she knew this information about each of them. She then continued with the rest of the basic procedure by telling each child to take one candy and excusing herself to work in another room while the child(ren) entered the room where the candy was. These procedures have been used several times before and require relatively little time. Because the children are asked their names at many other homes on Halloween, they do not seem to find the request strange. No attempt was made to identify any of the costumed children in the anonymous condition. The children were assigned to the anonymous and individuated conditions alternately by groups in each home.

Results

Of the 363 children, 70 (19.3%) transgressed by taking more than one candy.[2] Chil-

[1] The importance of these thoughts received anecdotal support by the statement of one parent to the children: "Oh, look, they have a mirror so you can all see your costumes. How nice."

[2] It should be noted that there are a number of possible ways to analyze the data. The overall rate of transgression can be computed for each relevant condition and contrasted with other conditions. Two other possibilities readily come to mind. One might just examine the behavior of the first child in each group, reasoning that those individuals will be *less*

Table 1
Percentage of Children Transgressing

Group	Condition	
	No mirror	Mirror
Individuated		
%	37.7	8.9
No. of children	69	90
Anonymous		
%	19.1	19.6
No. of children	68	97

dren arriving alone ($n = 39$) transgressed somewhat less frequently than groups of children did, 10.3% versus 20.4%, $z = 1.51$, $p < .07$. Since the distribution among all the various conditions of the few children who arrived alone resulted in sample sizes much too small for statistical analysis, and since the children who arrived alone seemed to transgress less often, the subsequent analyses of self-awareness effects are based upon the 324 children who arrived in groups.[3]

Self-Awareness and Deindividuation

Because of the apparently strong interaction between self-awareness and anonymity, an examination of the interaction by a z test on the arc sine transformation of the proportion differences (Langer & Abelson, 1972) was completed. The highly significant $z = 3.41$ ($p < .001$) revealed that there was indeed a strong interaction between the two variables, and so comparisons of individual conditions were computed. Children in the no mirror condition transgressed significantly more than those in the mirror condition, 28.5% versus 14.4%, $z = 3.10$, $p < .01$.[4] As is shown in Table 1, the self-awareness effect seemed only to occur in the individuation condition, where each child's identity was made salient. In the individuated, no mirror condition 37.7% of the children transgressed, compared to 8.9% in the individuated mirror condition, $z = 4.39$, $p < .0001$.[5] However, in the anonymous no mirror condition, 19.1% transgressed, compared to 19.6% in the anonymous mirror condition (*ns*).

Deindividuation theory would not only predict lower stealing rates for children who arrive alone (as was found) but would also predict that groups of children who are anonymous would steal more than groups consisting of individuated children. However, the data indicated that overall the anonymous groups actually produced a transgression rate, 19.4%, about equal to that for the individuated conditions, 21.4%. In the no mirror condition, the anonymous children stole significantly *less* often, 19.1% versus 37.7%, $z = 2.42$, $p < .02$, than individuated children did. However, in the mirror condition the individuated groups' norm violations were reduced below those of the anonymous groups

influenced by the group than the following children would be, and hence a more conservative analysis will emerge. One could instead assign a value to each group (such as the proportion of the group transgressing) and make groups, not individuals, the unit of observation. Since the group members certainly could influence each other, a group-as-unit analysis could be preferred. However, three important considerations argue for the use of the data from all individuals. First, past research employing the Halloween paradigm has found group and individual data to provide identical statistical outcomes. Second, since groups are comprised of mixed ages and sexes, hypotheses made concerning these variables could not be examined using groups as units. Third, the potential modeling effects (which work against independence of group members) require investigating each member's behavior, and this was one intent of the present design. Nevertheless, the analyses were performed when possible using the first child and also the proportion-per-group data. In almost every case the conclusions remained the same. These results will be noted in footnotes.

[3] Even though the manipulations were administered randomly with respect to sex, age, and group size, it is possible that the children did not arrive in a random pattern. Thus it would be possible for one of these variables to be disproportionately represented in some cells. Fortunately, such was not the case. The correlation of group size by condition was .096 (*ns*). The correlation for age by condition was .15 (*ns*). And the chi-square for the Sex × Condition interaction was .3 (*ns*).

[4] In the analysis using only first children, this comparison reached only marginal significance, 22.9% versus 12.9%, $z = 1.28$, $p < .10$. Using proportion data with groups as units for each group maintained significant results, $t(103) = 1.69$, $p < .05$.

[5] Data from first children yielded significant results, 35.3% versus 9.7%, $z = 2.16$, $p < .02$. Similar results occurred with the proportion data with group-as-units analysis, $t(50) = 2.95$, $p < .005$.

Table 2
Percentage of Individuated Children Transgressing as a Function of Age and Self-Awareness

Age (years)	Overall		No mirror		Mirror		
	%	*n*	%	*n*	%	*n*	*p*
1–4	0	11	0	5	0	6	*ns*
5–8	12.2	49	13.3	15	11.8	34	*ns*
9–12	27.0	63	46.4	28	11.4	35	.01
13 and above	40.0	20	72.7	11	0	9	.001

8.9% versus 19.6%, $z = 2.09$, $p < .05$. As will be discussed later, the unexpectedly low transgression rates among anonymous subjects have also occurred in several laboratory studies.

The results for the amount of candy taken per child replicated the earlier research of Diener, Fraser, Beaman, and Kelem (1976) in obtaining a mean of roughly three candies (two extra) for each transgressing child. They tend to take the amount their hands can hold easily. However, children in the condition with the reduced stealing rate, the *individuated* mirror condition, did take fewer candies compared to those in the individuated no mirror condition, 2.68 versus 2.0, $t(32) = 1.96$, $p < .05$, one-tailed. It appears that self-awareness reduced both the rates and the amount of candy taken when children were individuated.

Age Data

The median estimated age of the children was 8. Based upon the median, the age data were divided into four categories, 1–4, 5–8, 9–12, 13 and older, prior to examining the transgression data. These age categories were examined to investigate developmental trends. Analysis of the four categories indicated a significant age effect, $\chi^2(3) = 18.9$, $p < .001$, with the percentage of children stealing increasing over the four age categories, 6.5%, 9.7%, 23.6%, 41.9%, respectively. The finding of an increase of transgression with age should be interpreted cautiously, because it may be specific to the type of transgression involved, and there may be greater self-selection of those children who trick-or-treat in the older age groups.

More interesting, however, is the interaction between self-awareness and age. Self-awareness produced its largest effect on the transgressions of older children. Whereas self-awareness decreased the transgression rate by 55% among teenagers, $z = 3.06$, $p < .001$, it decreased transgression by only 15% for preadolescents, $z = 2.05$, $p < .02$, and not at all for younger children. Based on the overall analyses, these effects should be due to the behaviors of the individuated children, since apparently only these children were self-aware in the presence of the mirror. Table 2 presents the data for the individuated children. Again, the developmental trends were apparent. Self-awareness exerted its strongest influence on children aged 9 and above, and not at all on the younger children. Similar analyses done on the anonymous children (who we suspected were not made self-aware by mirror presence) yielded no significant difference at any age grouping.

Naturally Occurring Standards

The present design allowed an opportunity to examine the effect of self-awareness both on experimenter-imposed verbal standards and behaviorally set standards of peers (i.e., the behavior of the first child to approach the bowl could serve as a modeled standard for the rest of the children). All children received the experimenters' standard instructing them to take only one candy, and the results above reveal that self-awareness enhanced the impact of this norm. Peer-induced standards via the model effects were also apparent. Whatever the first child did in each group (transgress or not), a large percentage of subsequent children did also. Whereas children ex-

Table 3
Percentage of Children Not Transgressing as a Function of Modeled Behavior and Condition

Condition	Modeled behavior: Not transgress %	n	Transgress %	n
Individuated				
No mirror	76.9	26	50.0	12
Mirror	96.4	55	25.0	4
Anonymous				
No mirror	88.0	33	33.3	6
Mirror	89.0	54	36.4	11

posed to a first child who took more than one candy transgressed frequently (60.6%), those exposed to a nontransgressing model rarely did so, 10.7%, $\chi^2(1) = 41.6$, $p < .001$. In the anonymous condition *only* this modeling effect is apparent (see Table 3), once again revealing that the self-awareness manipulation had no effect for anonymous children. However, in the individuated condition where the mirror did affect behavior, the interaction with modeling is more interesting. The interaction was again analyzed by a z test on the differences in arc sine transformed proportions, and a significant value was found, 1.83, $p < .05$. Because of the use of a one-tailed test and the small sample in two cells, the Modeling × Self-Awareness interaction should be cautiously interpreted. It should be noted that the data in Table 3 for the mirror condition indicate that *both* self-awareness and modeling exerted effects on the self-aware children. That is, independent of the overall reduction in transgression caused by mirror presence, mirror presence also enhanced the tendency of subjects to conform to the behavior exhibited by the model.

Sex

The estimation of each child's sex was obtained for 326 of the children (including children who arrived alone, where age data were available). Due to their costumes, the sex data for the remaining 37 children could not be reliably determined. There were 190 boys and 136 girls. It was found that boys transgressed significantly more than girls, 24.2% versus 10.3%, $z = 3.16$, $p < .001$. The effect of the mirror were also examined for each sex. Boys' stealing rate decreased from 35.8% (no mirror) to 15.6% (mirror), $z = 3.2$, $p < .00$. The stealing rate for girls only dropped from 13.2% (no mirror) to 8.4% (mirror), $z = .87$, $p < .20$.

One last consideration pertains to a group size analysis. There were no differences in the transgression rates of the groups of various sizes (two to seven children), except for the high rate of 44% observed in groups of size five. Removing these groups from the analyses did not alter the significance levels of the analyses. It appeared that the high rate occurred because these few groups of five happened to occur only in no mirror conditions hence self-awareness was not present to reduce the transgressions. It should be emphasized again that since there was no other relationship between group size and transgression rates, the analyses are not influenced by the distribution of groups to various conditions. In a similar vein, the distribution of children of various ages to conditions was investigated and found to have no effect on the data analyses.

Discussion

As the theory of objective self-awareness predicts (Duval & Wicklund, 1972; Wicklund, 1975), standard-consistent behavior was increased in a naturalistic setting by focusing children's attention upon themselves. This occurred only when children had first been individuated by being asked their name and address. This reduction in transgression seems to reflect an increase in compliance to a salient behavioral standard. The standard instituted in the present study was the instruction given by the experimenter to "take one candy only." The children in the present study altered their behavior to be more consistent with the standard of correctness when they were self-aware. Thus the present findings add external validity to the earlier research showing greater adherence to standard-appropriate behaviors (Carver, 1974, 1975;

Diener & Wallbom, 1976; Scheier et al., 1974).

Anonymity

In cases where the children remained anonymous, the presence of the mirror had no impact on behavior. We interpret this as an indication that the child's focus of attention was directed to aspects of his/her costume rather than to the self. Hence, no state of self-awareness seemed to develop. Although these findings are consistent with the contention that anonymity may inhibit self-awareness, this may occur only in the presence of a disguise, not as a general function of anonymity. Future research in which self-awareness is induced and anonymity is experimentally manipulated in several different ways should help clarify the way in which anonymity affects self-awareness. It may be that when one is disguised and a group member, anonymity inhibits feelings of self-awareness. If one were alone in a costume on a downtown street at noon, the disguise might enhance self-awareness. Both the manner in which one is made anonymous and the situational context in which the anonymity occurs probably influence the effect this variable has on self-awareness.

Data from the anonymous conditions were not what one would predict from deindividuation theory (Zimbardo, 1970). It was hoped that the present study might, in addition to assessing various self-awareness effects, shed light on the interaction of the two theories. Earlier research (e.g., Diener et al., 1976) has shown that group presence, and also anonymity, increases transgressions. Although some weak support for increasing transgressions among groups compared to children arriving alone ($p < .07$) was found in the present study, no overall effects were found for anonymity. In fact, anonymous children actually transgressed significantly less in the no mirror condition than individuated children did (a similar result was also reported by Zimbardo, 1970, p. 277). One possible explanation for this is that in the present study the individuated no mirror condition may have had high rates of transgression due to some artifact introduced by the procedures used.[6]

A close inspection of the individuation literature reveals that previous results for anonymity effects have been quite mixed, with anonymity manipulations sometimes increasing and sometimes decreasing antinormative behavior (Diener, 1977). Thus our results are actually not inconsistent with the previous research findings. However, our findings do not illuminate why anonymity produced unexpected effects. The puzzle is heightened by the fact that our manipulation was identical to that used in an earlier study in which anonymity produced heightened transgression. Future research on anonymity should explore the interaction of other variables with anonymity in order to shed light on the past contradictory findings. One possible explanation of the problematical data in the anonymity versus individuated no mirror conditions is that asking children their name actually made salient to them the fact that they could not be easily identified by the experimenter, especially since she was rarely known by the children. Another possibility is that asking children their names heightened the children's awareness of the identity of others in their group, thereby enhancing cohesiveness, and thus possibly strengthened a transgressive norm if it was held by members of the group.

Development of Self-Awareness

One of the major benefits of this naturalistic study was the opportunity to gather data

[6] However, there are a number of considerations that rule against this possibility. First, the same individuation manipulation has been used by some of the authors in earlier research (e.g., Diener et al., 1976) which produced expected results. Thus we doubt that in this study the same manipulation would produce a radically different psychological state. Also, as mentioned earlier, asking children their names is not an unusual practice on Halloween. One might argue that sampling error led to the self-awareness effects. In order to provide an even more conservative test of the hypothesis, the anonymous no mirror transgression rate was used as a baseline to assess the decrease noted in the individuated mirror condition. Again, the mirror condition was shown to be significantly lower, 19.1% versus 8.9%, $z = 1.88$, $p < .04$. It thus appears unlikely that self-awareness results occurred due to some unknown artifact present in one of the individuated groups.

from children of various ages, thus allowing an examination of self-awareness from a developmental viewpoint. As was seen in Table 2, individuated children 8 years of age or younger were apparently unaffected by their self-reflections in the mirror. The mirror effects appeared to begin in our study somewhere around the age of 9, and then the effects were substantial. However, since stealing rates were lower among the younger children, it is possible that a floor effect was responsible for the absence of larger reductions in the lower age groups. Moreover, one must view the specific ages in our age data cautiously, as they are based on estimates. Further, our data do not indicate whether children under a given age do not enter the self-aware state or whether they have not yet gotten to the point where the presence of their reflection in a mirror cues other self-relevant thoughts. It seems relatively certain, though, that by ages 9–12, self-awareness has an effect in reducing transgressions, and by 13 and above self-awareness substantially reduces antinormative behavior.

Behavioral Standards

In the present study self-awareness could focus one's attention on a standard set by the experimenter and/or one set by the behavior of other children. The modeling effects were examined by analyzing the transgression rates for the children who approached the candy bowl after the first child (model) did in each group. If the first child did not transgress (honest model), 89.3% of the subsequent children were also honest. If the first child in a given group did transgress (dishonest model), the honesty rate was reduced to 39.4% for the followers. These effects replicate an earlier field study (Diener et al., 1976). However, these data are potentially confounded by the possibility that "honest" and "dishonest" children may tend to trick-or-treat together.

Self-awareness in the present study magnified the modeling effects, among individuated subjects. This Modeling × Mirror interaction should not be due to cohort effects, since the mirror was randomly assigned and cohorts should not have been any more similar in the mirror than the no mirror condition. Moreover, this finding suggests that the modeled behavior provided an additional norm at the time the followers approached the candy bowl. Carver (1974) has shown that aggression, which might normally be considered antinormative, can be facilitated by self-awareness in the laboratory if the salient standard of behavior favors aggressing. Our results in the field support Carver's in suggesting that transgressing can be enhanced by self-awareness (if the model makes salient a transgressing standard). The present results suggest that self-awareness can heighten the salience of norms implicit in the behavior of others, even when these norms are not verbally stated. However, because of the small sample size in the transgressive model groups, this interpretation should be accepted cautiously until replicated. Further research might vary orthogonally the types of standards in order to explore modeling further.

Summary

Overall, the findings form a consistent pattern of support relating antinormative behavior to the theory of objective self-awareness. An alternative explanation for the reduction of stealing in the mirror condition might be that the children were more worried about getting in trouble for taking extra candy when the mirror was present than when it was not. If this were the case, however, one would expect the fear of getting in trouble to be more salient in the individuated condition than in the anonymous conditions, since it was clear to the children that their names and addresses were known by the experimenter in the individuated condition. This explanation would predict a lower transgression rate in individuated no mirror conditions, compared to the anonymous conditions. Because such a result was not found, our self-awareness analysis offers a more complete explanation for the findings than does an analysis based on fear of reprisal.

Experiment 2

To add confidence to our interpretations, we designed a second study to replicate the

self-awareness findings. Thus, conditions were included where the standard of taking only one candy was made salient and self-focus was varied. In this second study, children were sent into the candy room one at a time, and all children were individuated by asking them their names and *ages*. The request-for-age information was used instead of asking their addresses in order to provide actual age data instead of estimates (as in Experiment 1). Finally, conditions were included in which no standard was made salient, to explore what standards, if any, may be present to guide childrens' behavior when trick-or-treating, without the experimenter's suggesting a specific behavior as appropriate.

It was hypothesized, as before, that mirror-induced self-awareness would decrease the percentage of children transgressing. The age trends revealed in Experiment 1 were expected to occur again with the *actual* ages given by the children. In the no standard conditions, the experimenter did not make any statement about the appropriate number of candies to take. We expected that children would be inclined to think that more than one candy was appropriate (since the candies were smaller than in Experiment 1, see below). Therefore, overall a larger percentage of children should take more than one candy in these conditions than in the standard conditions.

Whatever standard (if any) is common among trick-or-treaters should be most apparent in the no standard – mirror condition. These children should be self-aware and therefore more likely to behave consistently with the standards that they brought with them into the situation. One possibility is that children trick-or-treating on Halloween might think it is a night when they can "get all the free candy they want" or that "it is okay to steal." If such reasoning is correct and this sort of standard is salient, then *more* children in the no standard condition should take more than one candy in the mirror condition than would do so in the no mirror condition, since such behavior would be consistent with their standards. However, we believed it reasonable to suggest that children on Halloween have the cognitive set that they are to be "given free candy." Further, children realize that what they will receive at each house is governed by the people there. In addition, most children have in general an internal standard that it is inappropriate to take more than their own share or to steal. Thus we expected a *decrease* for the mirror condition in the number of candies taken. Which of these two possibilities is correct should be revealed by the directional difference between the no mirror and mirror conditions when no experimental standard was made salient.

Method

Participants and Setting

The participants were 349 children who arrived to trick-or-treat between 5:00 and 9:00 p.m. on Halloween, 1978, at any of 13 selected homes. Again, children were not used as subjects if they arrived with a parent or in groups too large to process or if a second group arrived before the manipulations could be completed on the group already present. The candy rooms were arranged as in Experiment 1.

Procedure

The greeting of children was performed as in Experiment 1. The children were sent into the candy room *one at a time*. The candy room was arranged such that the bowl of candy and child approaching it would not be visible to either the greeter or the other children waiting to enter the candy room. The hidden rater again recorded the number of candies taken. Instead of using age estimates, each child was individually asked his or her name and age and the greeter repeated this to the child prior to sending the child into the candy room. Thus all children were individuated. Based upon the results of Experiment 1, this appeared to be necessary as a precondition for self-awareness when the child was later in front of the mirror. Each child was alone at the candy bowl (thus each child's behavior was statistically independent of other children's).

Independent variables. Self-awareness was again manipulated by the presence or absence of a mirror. Mirrors were physically placed as in Experiment 1, and the same randomization procedures were used. To make a standard salient, children were instructed to take one candy only, as before. However, additional no standard conditions (for mirror and no mirror) were added. In these cases each child was told "the candies are in the living room, go help yourself." For these children the standard for behavior would be whatever norm(s) children generally have when trick-or-treating. The

Table 4
Percentage of Children Taking More Than One Candy and Mean Candies Taken

Verbal manipulation	Self-awareness		
	No mirror	Mirror	p
Standard			
%	34.2	11.7	.001
M	2.41	1.18	.001
No. of children	76	94

%	75.0	58.9	.03
M	4.56	2.17	.001
No. of children	84	95	

standard and no standard conditions were alternated at each house, so all four conditions were in operation at each house at various times throughout the evening.

Dependent variables. Again the percentage of children taking more than one candy was computed. Also the exact number of candies taken by each child was recorded. In Experiment 1, small bite-sized candy bars were used. However, the transgression rate (more than one candy) was relatively low (about 10% for individuated children who arrived alone). Thus it was decided to use smaller candies for this study, to produce a higher transgression base rate, so that decreases caused by self-awareness could more easily be discerned. Several types of candies were chosen that varied in size between that of an individually-wrapped caramel and the candy size used before. This choice should also allow for a more sensitive measure, since the size of a child's hand would not limit as much the number of candies taken.

Results

Mirror Effects

Of the 349 children, 156 (44.7%) took more than one candy. The effectiveness of the verbally stated standard to take only one candy is shown by the highly significant reduction in the standard conditions when compared to the no standard conditions, 21.8% versus 66.5%, $\chi^2(1) = 68.7$, $p < .001$. Similarly, over all conditions the mirror produced a strong reduction inhibiting children from taking more than one candy, 55.6% versus 35.4%, $\chi^2(1) = 37.5$, $p < .001$. However, the comparisons of most interest were those within each of the types of standards.

The percentages of children taking more than one candy and the mean number taken are shown in Table 4. Transgressions were greatly reduced by the mirror, $\chi^2(1) = 11.2$, $p < .001$, when the standard was made salient by the experimenter. The reduction in numbers of candies taken was also significant, $t(168) = 3.29$, $p < .001$. Even though children were not given specific instructions in the no standard condition, fewer children took more than one candy when a mirror was present than when it was not, $\chi^2(1) = 4.5$, $p < .03$, and children took fewer candies on the average, $t(177) = 3.89$, $p < .001$.

Age Data

As is shown in Table 5, self-awareness affected the older children when a standard had been made salient, but not the younger ones. These results compare favorably with Experiment 1, where age estimates were used instead of actual age, as in the present study.[7] Similarly, the presence of the mirror reduced transgressions for the two oldest age categories when no standard was made salient. These decreases did not reach statistical significance.

Sex Data

Overall, there was only a marginal tendency for males to take two or more candies more frequently than females, 49.0% versus 39.7%, $\chi^2(1) = 2.59$, $p < .11$. However, if we examine only the standard conditions, where such behavior may more clearly be labeled a transgression, we find that males did transgress more, 28% versus 13%, $\chi^2(1) = 4.5$, $p < .03$, as was the case in Experiment 1. Also as before, self-awareness in this condition reduced the proportion of male transgressors from 46.8% to 11.3%, $\chi^2(1) = 13.9$, $p < .001$, whereas the reduction was nonsignificant among females (14.3% to 12.2%).

[7] The accuracy of these estimates is not of major concern with respect to the present data. Nevertheless, an estimate of their reliability may be of interest for future research. A correlation coefficient of 0.89 was obtained (based on several homes that included an extra experimenter who independently estimated ages to provide reliability data), indicating a high relationship between estimates and actual age.

Table 5
Percentage of Children in the Standard Conditions Taking More Than One Candy as a Function of Age and Self-Awareness

	Condition				
	No mirror		Mirror		
Age (years)	%	*n*	%	*n*	*p*

5–8	40	20	25	32	*ns*
9–12	24	25	6.1	33	.04
13 and above	50	24	0	16	.001

Discussion

Since all findings in the second experiment replicated the earlier findings, only the extension and additions will be discussed here, in order to avoid redundancies. Overall, self-awareness again exerted a strong influence on children aged 9 and older. The self-awareness results in Experiment 2 are especially reassuring in that they were clearly unconfounded by modeling effects, since children entered the room individually. The use of actual age data supported the former estimated age findings. The mirror-induced self-awareness effect simply was not present among young children. Why this was so should be an important subject for future research.

The addition of no standard conditions, where children were not given an instruction as to how many candies they might take, yielded two important conclusions. First, the saliency of the simple verbal statement to take just one candy was demonstrated by the large reduction in the standard condition compared to the no standard condition. Second, the first evidence was provided concerning the cognitive standards by which children may generally guide their behavior in this particular setting. Apparently Halloween is a night when a child receives free candy, but that fact does not remove his/her knowledge that it is inappropriate to overindulge or to steal.

It should be reiterated at this point that although the term "transgression" has a moralistic connotation, the theory of self-awareness is a neutral one. It may be in our study that self-awareness inhibits transgressions or increases conformity to standards. Children who transgress may not be so much actively breaking rules as just failing to self-regulate. Self-awareness may be one of many variables that aid in producing self-monitoring of one's behavior. The theory has been primarily developed in terms of producing a state where one evaluates his or her behavior in terms of how consistent it is with salient social or personal standards. In such states one should act in ways that are more consistent with whatever standards are salient and are seen as applying in that situation.

In sum, the present two large-scale field studies offer strong support for the theory of self-awareness as applied to transgressive behavior among children. The first study also provided some leads concerning modeling that should be followed up in future laboratory studies. Finally, the age effects should also encourage researchers to study the developmental course of self-awareness.

Variation in Behavior Perception and Ability Attribution

Darren Newtson and Richard J. Rindner
University of Virginia

Three studies were conducted. In the first, 16 subjects segmented a videotape of an actor solving 30 problems in an ascending success pattern under instructions to analyze the first half of the sequence into fine or large units. Estimates of future performance were lower when the initial part of the series was analyzed more finely. In a second study, 72 subjects viewed either an ascending or a descending success pattern; the first half of the series was presented at fast motion, normal speed, or slow motion. Slow-motion presentation induced finer units of analysis than normal speed and enhanced primacy effects; fast motion induced larger units of analysis and attenuated primacy effects. A third study compared fine-unit and large-unit analysis induced by instruction and large-unit analysis induced by fast-motion presentation of the entire ascending and descending series. Results were comparable to those of the first two studies. It was concluded that primacy effects result from a cessation of processing when a point of subjectively sufficient information is reached and that variations in level of analysis set limits on information gain in observation.

Results of several recent studies of behavior perception have supported the view that actions are discriminated by the selection of successive points of definition in the behavior stream. These points of definition, termed breakpoints, are points judged by perceivers as the points at which actions have occurred (Newtson, Engquist, & Bois, 1977; Newtson, Rindner, Miller, & LaCross, 1978). Breakpoints appear to be selected in such a way that they provide a summary of the information gained from observation of the sequence of events (Newtson & Engquist, 1976).

Newtson (1973) hypothesized that perceivers actively control information gain from behavior by selecting a greater or lesser number of breakpoints from the behavior stream. That is, observers selecting more breakpoints from a given sequence (i.e., analyzing the behavior into finer units of action) should gain more information than observers analyzing the behavior into larger units. Newtson (1973) in fact did find that subjects instructed to analyze a 5-minute action sequence into fine units had more confident and differentiated impressions of the stimulus person than those subjects instructed to analyze that behavior into large units. In a second study, it was found that the occurrence of an unexpected event prompted observers to analyze subsequent behavior more finely than observers who had not viewed the unexpected action. This result is also consistent with the view that observers actively control information gain from ongoing behavior. In the control condition of that study, where the behavior remained predictable throughout, a marked decline in number of breakpoints was observed from the beginning to the end of the sequence. Wilder (1978a) reported a similar decline in rate of segmentation over time.

Newtson (1973) noted that one consequence of this decline over time could be that the perceiver's sample of information is biased, in that it would be largely drawn from

the first part of a sequence. Thus one might predict primacy effects in attributions based on the observation of behavior. Newtson (1973) raised this possibility as one alternative explanation for the primacy effects in ability attribution reported by Jones, Rock, Shaver, Goethals, and Ward (1968).

The present article reports a series of studies exploring such biased sampling phenomena. Biased sampling was induced in two different ways: by instruction as to level of perceptual analysis, as in Newtson (1973), and by variations in film speed. Filmmakers have long defined a quantity termed *event density* in terms of the number of events happening within a certain time unit. Slow- and accelerated-motion techniques are explicitly defined as manipulations more of event density than of motion and may be realized equivalently with both cutting techniques and actual manipulation of film speed (cf. Zettl, 1973, pp. 280–283). Variations in level of analysis may be thought of as subjective variations in event density that are under the perceiver's control. Thus film speed manipulations may provide a useful converging operation for the manipulation of level of perceptual analysis, although their precise effects on interpretation of events remain to be evaluated.

Experiment 1

In the first experiment, subjects viewed an actor attempting to solve 30 problems, succeeding on 5 of the first 15 and on 10 of the last 15. In one condition, subjects were instructed to analyze the series into fine units for the first half of the series and then into whatever units seemed natural and meaningful to them for the second half of the series. In a second condition, subjects analyzed the series into large units for the first half and then into natural units for the second half of the series. Subjects were next asked to make estimates of the actor's performance on a subsequent series of problems. Thus, it was reasoned, the subjects' information sample from the initial part of the series should be increased or decreased. The result should be that the impact of the initial part of the series on estimates of the actor's future performance should be greater when it is analyzed finely and less when it is analyzed into large units.

Method

Subjects. Subjects were 16 undergraduates (12 males, 4 females) recruited from an introductory psychology course at the University of Virginia.

Stimulus. A videotape was prepared showing a male actor ostensibly taking a computer-scored intelligence test. The actor read each question from a 3 × 5 inch (7.62 × 12.70 cm) card and typed a response into a teletype. Feedback was presented by means of two lights above prominent signs labeled "right" or "wrong." Thirty items were answered in this manner. The actor received "right" feedback on 5 of the first 15 items and on 10 of the second 15 items. The specific feedback pattern was as follows: 1 "right," 4 "wrong," 1 "right," 3 "wrong," 2 "right," 2 "wrong," 1 "right," 2 "wrong," 3 "right," 3 "wrong," 3 "right," 1 "wrong," and 4 "right."

Procedure. Subjects were assembled in groups of two or three persons facing a 23-inch (58 cm) video monitor. Each subject was given a hand-held button connected to an event recorder in another room. Subjects were informed that they would view a videotape of another undergraduate taking a computer-scored intelligence test. All subjects were then instructed as follows: "What I am interested in here are the ways in which people organize or break up another person's behavior into its component actions. By that I mean that people may break up another person's behavior in different ways. For example, he might turn, walk over, push a door closed, turn and walk back, and you might see each of those actions as a separate, meaningful action. Or you might see them as just one action, such as closing the door. In one condition, subjects were then instructed, "What I would like you to do is to mark off for me the *largest* actions in the sequence you will shortly see, as you see them. That is, I want you to press this button firmly whenever, in your judgment, such a meaningful action occurs. There are no right or wrong ways to do this; I simply want to know how you do it."

In the second condition, subjects were given the same instructions, except that the word *smallest* was substituted for *largest*.

At the midpoint of the sequence the tape was halted, and all subjects were instructed, "From now on, I want you to mark off whatever actions seem natural and meaningful to you."

Dependent measures. Data consisted of the number of breakpoints marked for each half of the videotape and responses to the postexperimental questionnaire items. The first item asked subjects to estimate the percent correct that the stimulus person would obtain on a second series of similar items. A second

question asked subjects to report the number of items the stimulus person had answered in the videotape. A third item asked subjects to recall the percentage of those items the stimulus person got right.

An additional comparison of the unit data was conducted to see if the predicted differences in level of analysis varied over a hierarchical structure. Frequencies of marking were tabulated for each 1-sec interval of the sequence. If fine-unit subjects are simply breaking down into smaller components the same actions that subjects using larger units are discriminating, then it follows that where the large-unit condition subjects indicate a breakpoint in the sequence, fine-unit subjects should agree, also indicating a breakpoint (note that the converse need not necessarily be true). Accordingly, consensus breakpoints in the large-unit condition were identified, and the frequency of identification of these same points as breakpoints in the fine-unit condition was compared to chance expectation by chi-squares (see Newtson, 1973). Statistical confirmation of the hypothesis would indicate a significant tendency toward a hierarchical relationship between the two segmentations.

Results

Subjects viewing the first part of the sequence under fine-unit instructions marked an average of 50.13 units, which was significantly more than the quantity subjects marked under large-unit instructions, $M = 18.88$, $t(14) = 5.83$, $p < .001$. Number of units did not differ significantly for the second half of the tape; means were 43.38 and 43.50 for the fine-unit/natural-unit and large-unit/natural-unit conditions respectively, $t(14) = .023$.

Subjects in the fine-unit/natural-unit condition estimated future performance at 35.75%, significantly worse than subjects in the large-unit/natural-unit condition, $M = 61.88$, $t(14) = 3.34$, $p < .01$. Results on recall of past performance were in the same direction, although this difference did not attain significance; means were 34.50 and 43.75, $t(14) = 1.69$, $p < .20$, two-tailed, for the fine-unit/natural-unit and large-unit/natural-unit conditions, respectively.

Comparison of segmentation patterns confirmed the hypothesis that fine-unit and large-unit segmentations would be more hierarchically related than chance, $\chi^2(1) = 9.46$, $p < .01$. That is, fine-unit subjects tended to break down the actions discriminated in the large-unit conditions into their component parts.

Discussion

These results confirmed that variation in level of analysis systematically altered the impact of the behavior on observer judgments. When the initial part of the series was analyzed finely, subjects predicted significantly poorer subsequent performance than when the first part of the series was analyzed in larger units. These results raise the possibility that biased information sampling could underlie primacy effects in ability attribution in the Jones et al. (1968) paradigm.

Evaluation of this hypothesis requires a comparison of the segmentations between the first and second halves of both an ascending and a descending success series. If the biased sampling interpretation is correct, then more breakpoints should be discriminated in the first halves of the sequences than in the second halves, and a typical primacy effect should result. That is, subjects viewing a series in which rate of success is low at the outset and then improves should estimate future performance as poorer than subjects viewing a series in which rate of success begins at a high level and then declines.

In addition, film speed was varied for the first halves of the sequences. The first half of each sequence was presented in slow motion or in fast motion. Our ability to comprehend variable speed films is an interesting phenomenon. Rate of movement in fast-motion and slow-motion films is typically altered by a factor of 7 to 10 times (cf. Miller & Strenge, 1969). This ability has simply not been explained. A careful search of the literature has failed to yield a single study systematically investigating the effects of film speed on the perception or interpretation of action. If, as suggested earlier, manipulations of film speed are similar in important ways to normal variations in level of perceptual analysis, variable speed film techniques may provide a useful convergent operation for the manipulation of level of perceptual analysis that is free of at least some of the possible demand characteristics associated with direct instructions. It would seem reasonable to expect that slow-motion film presentation would induce fine-unit analysis of a behavior sequence, whereas

fast-motion presentation would induce large-unit analysis.

Experiment 2

In this experiment subjects viewed one of two sequences showing an actor attempting to solve 30 problems. One sequence was the ascending success series employed in Experiment 1. A second sequence showing a descending success series was included in this experiment. The first half of each sequence was shown to subjects at slow motion, normal speed, or fast motion. In all conditions, the second halves of the sequences were shown at normal speed. It was anticipated that slow-motion presentation should induce finer unit analysis than normal speed presentation and that fast-motion presentation should induce larger unit analysis.

Results from the previous study suggest that the number of units marked for the first half of the series determines the impact of that part of the series in subsequent judgments. It would follow, therefore, that slow-motion presentation should enhance primacy effects as compared to normal-speed presentation, whereas fast-motion presentation should attenuate primacy effects. Alternately, the differences observed in Experiment 1 could have been unidirectional, such that only one of the instructional conditions affected judgments as compared to normal observation.

Method

Subjects. Seventy-two male undergraduates served as subjects in the experiment.

Stimuli. The study employed the ascending success sequence from the previous experiment and a second, descending success sequence. In this sequence, the actor received "right" feedback on 10 of the first 15 problems, and on 5 of the last 15. The precise pattern of feedback for this sequence was simply the reverse of the pattern for the ascending success series.

Three versions of each series comprised the stimuli for the experiment. One version simply consisted of the entire sequence of 30 problems at normal speed (normal-speed conditions). In a second version, the actor's performance on the first 15 items was copied at seven times normal speed, and the last 15 responses were recorded at normal speed (fast-motion conditions). In a third version, first-half performance was copied at one-seventh speed, whereas the second half was recorded at normal speed (slow-motion conditions).

This resulted in sequences of the following lengths: normal speed, 10.1 min.; slow motion, 42.4 min.; fast motion, 5.9 min.

Selection of these film speeds was dictated by available videotape machinery. Video recorders with continuously variable speed capacity also have "frame roll": each video "frame" is presented successively with a black bar separating them. The machine used for this experiment (a Javelin) is capable of presenting videotapes at 7:1 and 1:7 speeds without frame roll but is limited to these fixed presentation speeds.

Procedure. Subjects were assembled in groups of randomly varying size (1 to 15 persons) facing a 23-inch (58 cm) video monitor. Each subject was given a hand-held button, connected to an event recorder in another room. Subjects were informed that they would view a film of another undergraduate taking a computer-scored intelligence test. All subjects were then given the same segmentation instructions as in Experiment 1, except that subjects were instructed to discriminate the "naturally occurring" actions in the sequence.

Finally subjects were informed that sequences would be presented at varying speeds and were told the speed of the tape that they were about to see. This was done in order to prevent "surprise" effects on marking and to prepare subjects (especially in the fast-motion condition) for marking.

Following the viewing of the tape, subjects completed a questionnaire and were then debriefed.

Dependent measures. The same postexperimental questionnaire was used as in the previous study.

Design and analysis. Number of breakpoints marked for the sequences were analyzed in a $2 \times 2 \times 2$ mixed-effects analysis of variance in which there were two between-subjects factors, success pattern (ascending vs. descending) and speed of presentation (slow, normal, and fast motion) for the first half of the sequences, and a repeated measure film half (first vs. second).

Responses to postexperimental questionnaire items were analyzed in a 2×3 analysis of variance design in which factors were success pattern (ascending vs. descending) and speed of presentation (slow, normal, and fast motion).

Segmentation patterns for the first halves of the films were analyzed as in Experiment 1. This analysis is rather more important in the present study, as it bears on the question of whether or not the film speed manipulations simply disrupted perception of the sequences. Frequencies of marking were tabulated for each 1-sec interval, as before, and consensus breakpoints were identified for each sequence in each condition. Since presentation speed in the fast-motion condition was seven times that of normal-speed presentation, each 1-sec interval of the fast-motion record corresponded to seven 1-sec intervals in the normal-speed condition. Accordingly, co-occurrences of breakpoints were identified according to the following criterion: if an interval was identified as

Table 1
Mean Number of Breakpoints by Success Pattern, Speed of Presentation, and Film Half

Speed	Success pattern					
	Ascending		Descending		Combined average	
	First half	Second half	First half	Second half	First half	Second half
Slow	73.82	65.36	79.42	61.00	76.74_a	63.09_b
Normal	38.46	36.00	55.08	48.42	47.13_c	42.48_c
Fast	21.17	42.42	26.83	43.58	24.00_d	43.00_c

Note. Speed of presentation varied for the first film half only. Means with different subscripts differ by t test, $p < .001$.

breakpoint in the fast-motion condition, then the occurrence of a breakpoint in the normal-speed condition in any of the corresponding seven 1-sec intervals was counted as one, and only one, co-occurrence. Comparison of segmentations between the normal-speed and slow-motion conditions was performed in a completely analogous manner. Statistical confirmation of these hypotheses would indicate a significant tendency toward a hierarchical structure in the segmentation of the behavior.

Results

Unit data. Analysis of variance of unit data indicated a significant main effect for speed of presentation, $F(2, 64) = 23.46$, $p < .001$, and a significant Speed of Presentation × Film Half interaction, $F(2, 64) = 27.15$, $p < .001$. The main effect for success pattern, $F(1, 64) = 1.93$, $p < .20$, and the interaction between this factor and film half, $F(1, 64) = 2.81$, $p < .10$, approached significance. No other effects or interactions approached significance. Means are reported in Table 1. Interaction means are reported so as to facilitate comparison with Experiment 1, which employed the ascending success series only. The biased sampling hypothesis predicts that at normal speed more units should be marked for the first halves than the second halves. This hypothesis was not supported. When the sequence was presented at normal speed, unitization of the two film halves did not differ significantly, $t(64) = 1.45$, $p < .20$.

Under slow motion, more units were marked for the first than the second halves of the sequences, $t(64) = 4.24$, $p < .001$, which were at normal speed. When the first halves of the sequences were presented at fast motion, significantly fewer units were marked for the first halves of the sequences, $t(64) = 5.91$, $p < .001$. It was predicted that speed of presentation would alter level of unitization for the first halves of the sequences. Comparison of these means using t tests confirmed that more units were marked under slow motion than normal speed, $t(64) = 9.20$, $p < .001$, and more units were marked at normal speed than at fast motion, $t(64) = 7.91$, $p < .001$.

An unexpected result was obtained for the second half of the films in the slow-motion condition. Apparently because they had been induced to analyze the behavior finely in the first half by the slow-motion presentation, subjects persisted in finer unit analysis than that performed in the other condition (see Table 1).

Comparisons of segmentation patterns for the first halves of each sequence across film speeds indicated that the film speeds simply altered segmentations over a hierarchical structure. For the ascending series, 90% of the breakpoints marked under fast motion were also marked at normal speed, $\chi^2(1) = 153.31$, $p < .001$, whereas 45% of the breakpoints marked at normal speed were also marked at slow motion, $\chi^2(1) = 35.78$, $p < .001$. In the descending series, 60% of the breakpoints identified at fast motion were also breakpoints at normal speed, $\chi^2(1) = 63.68$, $p < .001$, whereas 64% of the breakpoints marked at normal speed were also breakpoints at slow motion, $\chi^2(1) = 56.43$, $p < .001$. This level of consensus is comparable to that observed for different levels of segmentation in previous studies (cf. Newtson, Enquist, & Bois, 1976). These results confirm that the film speed manipulations were not so

Table 2
Mean Estimates of Future Performance, Number of Problems Attempted, and Percent Correct by Speed of Presentation and Success Series

Success pattern and speed of presentation	Measure		
	Future performance (% correct)	% correct	No. attempted
Ascending			
Slow	35.97	32.27	23.82
Natural	46.36	39.09	27.91
Fast	67.08	60.00	27.33
Descending			
Slow	71.83	69.33	24.67
Natural	64.58	60.00	24.42
Fast	45.42	43.75	27.08

Note. Speed of presentation varied for the first film half only.

extreme as to disrupt perception of the sequences but that they did, as hypothesized, alter level of perceptual organization in a lawful manner.

Estimates of future performance. Analysis of variance of estimates of future performance indicated a significant main effect for success pattern, $F(1, 64) = 13.78$, $p < .001$, and a significant interaction between this factor and speed of presentation, $F(2, 64) = 34.11$, $p < .001$. The main effect of speed of presentation was not significant ($F < 1$). Means for this measure and two others are presented in Table 2. Comparison of the means in the natural-speed conditions across the ascending and descending success patterns indicated a strong primacy effect. Subjects viewing the ascending success series predicted significantly poorer subsequent performance than subjects viewing the descending success series, $t(64) = 3.61$, $p < .01$. This result replicates the findings of Jones et al. (1968).

It was predicted that slow-motion presentation of the first halves of the series would accentuate primacy effects. In the ascending series condition, slow-motion presentation resulted in significantly lower estimates of future performance than natural-speed presentation, $t(64) = 2.07$, $p < .05$, as expected. In the descending series condition, however, while slow-motion presentation tended to produce higher estimates of future performance, this difference was only of marginal significance, $t(64) = 1.44$, $p < .10$, one-tailed.

The second prediction, that fast motion should reduce primacy effects, was unequivocally supported. In the ascending series condition, fast-motion presentation resulted in significantly higher estimates of performance than natural-speed presentation, $t(64) = 4.10$, $p < .001$. In the descending series condition, fast-motion presentation resulted in significantly lower estimates of future performance, $t(64) = 3.79$, $p < .001$.

Recall of percent correct. A second questionnaire item asked subjects to recall the percentage of problems that the stimulus person had gotten right. Results on this measure generally paralleled those of the first but were slightly weaker statistically. A significant primacy effect was again obtained in the natural-speed conditions on this measure (see Table 2), with subjects recalling better performance in the descending series than in the ascending series conditions, $t(64) = 3.92$, $p < .001$.

As on the previous measure, differences between slow-motion presentation and natural speed were consistently in the predicted direction. In the ascending condition, the difference in recall of number correct did not differ significantly between the natural and slow-motion conditions, $t(64) = 1.28$, $p < .15$, one-tailed, although this difference did attain significance in the descending condition, $t(64) = 1.75$, $p < .05$, one-tailed.

Comparison of the fast-motion and natural-speed presentation conditions confirmed the predicted effect on this measure. Subjects in the natural-speed conditions recalled significantly lower performance than fast-motion condition subjects from the ascending series, $t(64) = 3.92$, $p < .001$, and recalled significantly higher performance at natural speed from the descending series than at fast motion, $t(64) = 3.04$, $p < .01$.

A third item requested subjects to recall the number of items attempted. Analysis of variance of these responses indicated no significant main effects or interactions. Means are reported in Table 2. Apparently, the ve

iations in film speed did not alter perception of problems attempted.

Discussion

Results did not support a simple biased sampling interpretation of primacy effects in ability attribution. Differences in number of units marked between sequence halves were small, despite a strong replication of the Jones et al. (1968) primacy effect on the cognitive measures. This failure to confirm the hypothesis is especially intriguing in view of the significant impact of the film speed manipulations on primacy effects in the second experiment, and the effects of level of analysis in Experiment 1.

Comparisons between the two experiments are also interesting in view of the tremendous differences in processing time between the two experiments. Subjects viewing the first half of the ascending success series under fine-unit instructions estimated future performance ($M = 35.75$) as comparable to those viewing that part of the sequence under slow motion ($M = 35.91$). Similarly, estimates of future performance resulting from large-unit instructions ($M = 61.88$) closely paralleled those obtained when the initial part of the sequence was presented in fast motion ($M = 67.08$). As the sequences were about 10 minutes long, the first half took 35 minutes to view at slow motion and about 43 seconds at fast motion.

Despite the large differences in presentation time, analysis of segmentation patterns confirmed that the fast-motion and slow-motion presentations did not destroy the intelligibility of the event. No differences were observed on estimates of the number of problems attempted, although it might be argued that subjects in all conditions inferred that the sequences were divided in half for presentation and simply doubled their estimates from the second halves of the films. More simply, however, inspection of the films themselves revealed no difficulty in following the events. These film speeds might be considered extreme. As indicated by their choice as a fixed speed by the manufacturer of the video recorder, however, these speeds are fairly typical for fast-motion and slow-motion film presentations.

The comparability of the instructional variations and film speed variations on the perceptual and cognitive measures does not indicate that there was some fortuitous "match" between the film speeds used and these instructional extremes. Rather, a hierarchy of structures exists in behavior, in this instance at a step-by-step level, at a trial-by-trial level and, as suggested by the natural-speed conditions, at at least one intermediate level. The variations in film speed apparently caused observers to select the level of analysis that was least difficult to employ under the circumstances.

With respect to the mechanisms of information integration underlying the cognitive data, the present findings are suggestive, if not conclusive. One possibility could be a simple kind of attention decrement or enhancement effect. That is, if fine units provide more information to the observer, subjects in the fine-unit/natural-unit and slow-motion/normal-speed conditions would have, in comparison to subjects in the normal-speed conditions, a sample of information from the behavior that is biased toward the first part of the sequence. For this to occur, however, it would also be necessary for perceivers to weight outcomes according to the number of actions associated with them. That is, one would have to assume that the experience of following someone through a step-by-step problem-solving attempt and then seeing him or her fail causes the outcome (i.e., the failure) to have more impact on the perceiver's judgment than if the perceiver viewed the event in large units of action (e.g., the actor tried and failed). The smaller magnitude of differences between the slow-motion/normal-speed conditions and the normal-speed conditions could thus be seen to follow from the fact that fine-unit analysis tended to persist in the slow-motion/normal-speed conditions. This interpretation could not, however, account for the occurrence of primacy effects in the normal-speed conditions, since segmentation did not differ across film halves in these conditions. Thus such an interpretation would have to assume that these effects occur in addition to primacy effects due to other mechanisms.

A second, perhaps more likely interpreta-

tion is that differences in level of analysis affect the point in the series at which a subjectively sufficient quantity of information is reached. That is, observers in these studies are simply told to view the series of events. If we assume, following Jones and Davis (1965), that perceivers take in information about others only until they feel they have "reason enough" to predict or explain the other's behavior, then it could be that fine-unit perceivers obtain sufficient information (subjectively) about the actor sooner in the series than large-unit perceivers. This could include other information about the actor than just ability information as reflected in outcomes of trials. Since the distribution of outcome information in the series is biased, the sooner the perceiver stops incorporating new information, the poorer (in an ascending success series) the impression of the actor's ability would be. This interpretation would have the advantage of being a more parsimonious one and might also account for the parallel results on both estimates of future performance and on recall of number of problems solved, in the absence of differences in recall of number of problems attempted. That is, although subjects continued to monitor the problem-solving behavior throughout the series, it would appear that they ceased to integrate outcome information into their impression of the actor's ability beyond a certain point.

It might be argued, however, that the results on the cognitive measures in both experiments are artifactual, in that there was a confound between the shift in content between film halves (the changing success rate) and the shift in instructions (Experiment 1) or in film speed (Experiment 2). That is, perhaps the changes in instruction or film speed caused subjects to conclude that the second half of the sequences was more or less important. A third experiment was thus conducted to rule out this interpretation.

Experiment 3

In this experiment subjects viewed either the ascending or descending success series. Subjects were instructed to analyze normal-speed films into fine units or large units or to segment fast-motion films naturally. The same segmentation instructions and film speed were maintained throughout the series. If the results on the cognitive measures in the first two experiments were due to an artifact of changes in film speeds or instructions, differences on these measures as a function of these manipulations should not be observed. Failure to find accentuation or attenuation of primacy effects as a result of these manipulations, however, could also be consistent with the interpretation of the previous results as due to enhancement of or decrements in attention. That is, if level of analysis simply affects the weighting of outcomes throughout the series, then differences in levels of analysis, if maintained throughout, should leave the overall judgment unchanged.

If, however, differences in level of analysis affect the point in the series where information integration ceases, fine-unit analysis should produce strong primacy effects, whereas large-unit analysis should attenuate them.

The present study did not include slow-motion conditions. Slow-motion presentation of these sequences would take more than 70 minutes. Our experience with the previous study suggested that slow-motion presentation of only the first halves of the sequences tested the limits of human endurance. Since the fast-motion conditions are adequate to test the alternative interpretations noted above, slow-motion conditions were excluded.

Method

Subjects. Subjects were 53 undergraduates (20 males, 33 females).

Stimuli. The same sequences were used that were employed in the previous study. Two versions of each sequence were used: (a) the normal-speed version of the ascending and descending series (length was 10.1 min.), and (b) a fast-motion version, in which the entire sequence was presented at seven times normal speed (length was 1.45 min.).

Procedure. Subjects in the fine-unit and large-unit conditions were instructed as in Experiment 1; subjects in the fast-motion conditions were instructed as in Experiment 2. One alteration in the procedure was made from the previous two studies. Subjects were asked to record units by making marks on a piece of paper, rather than by pressing a button as in the previous two studies. This modification of the recording procedure has been used by Wilder (1978a,

Table 3
Mean Number of Breakpoints, Estimates of Future Performance, Recall of Percent Correct, and Recall of Number of Problems Attempted by Condition and Success Series

Success pattern and condition	Measure			
	Number of breakpoints	Future performnace	% correct	No. attempted
Ascending

1978b) with good results and is more efficient if one is primarily concerned with the number, rather than the patterning, of breakpoints.

Dependent measures. The same postexperimental questionnaire was used as in the previous study.

Design and analysis. A one-way analysis of variance was conducted between the six groups (fine-unit, large-unit, and fast-motion conditions for the ascending and descending series) to obtain an estimate of variance, and t tests were conducted between groups on each of the variables.

Results

Results of the one-way analyses of variance indicated significant differences between groups in number of breakpoints marked, $F(5, 47) = 13.11$, $p < .001$; estimates of future performance, $F(5, 47) = 21.94$, $p < .001$; and recall of percent correct, $F(5, 47) = 9.05$, $p < .001$. As in the previous studies, no significant differences were obtained between groups on recall of number of problems attempted, $F(5, 47) = .40$.

Means for the six groups on all measures are reported in Table 3. Tests of mean differences indicated that for the ascending success series, significantly more breakpoints were marked in the fine-unit condition than in the large-unit condition, $t(47) = 3.33$, $p < .005$, or in the fast-motion condition, $t(47) = 1.85$, $p < .05$, one-tailed. Number of breakpoints marked did not differ between the large-unit and fast-motion conditions for the ascending series, $t(47) = 1.29$, $p < .20$.

Similarly, in the descending success series conditions, significantly more breakpoints were marked in the fine-unit condition than in the large-unit condition, $t(47) = 5.86$, $p < .001$, or in the fast-motion condition, $t(47) = 6.53$, $p < .001$. The latter two conditions did not differ in number of breakpoints marked, $t(47) = .25$, $p < .80$.

Results on estimates of future performance paralleled those obtained in the previous two studies, ruling out interpretation of those results as due to artifacts or attentional variations. In the ascending series, subjects in the fine-unit condition predicted significantly lower performance than subjects in the large-unit, $t(47) = 4.26$, $p < .001$, or in the fast-motion, $t(47) = 4.83$, $p < .001$, conditions. Fast-motion and large-unit condition means did not differ, $t(47) = .81$, $p < .40$.

Results on this measure in the descending series conditions indicated significantly higher estimates of future performance in the fine-unit condition than in the large-unit, $t(47) = 5.99$, $p < .001$, or in the fast-motion, $t(47) = 8.35$, $p < .001$, conditions. The difference between the large-unit and fast-motion conditions did not quite attain significance, $t(47) = 1.81$, $p < .10$.

The measure of recall of past performance produced results similar to those on the previous measure. In the ascending series conditions, mean recall of past performance was significantly lower in the fine-unit condition than in the large-unit condition, $t(47) = 2.98$, $p < .005$, or in the fast-motion condition, $t(47) = 3.22$, $p < .005$. Recall of past performance did not differ between the large-unit and fast-motion conditions, $t(47) = .41$, $p < .70$.

In the descending series conditions, recall of past performance was significantly higher in the fine-unit condition than in the large-unit, $t(47) = 1.96$, $p < .05$, or in the fast-motion, $t(47) = 5.25$, $p < .001$, conditions. The difference between the large-unit and fast-motion conditions, which was marginally significant on estimates of future performance, attained significance on this measure, $t(47) = 2.95$, $p < .005$.

Discussion

Since the same film speed and instructional conditions were maintained throughout the series in this experiment, subjects could not have responded to a demand that they weight the performance in the series unequally. This rules out a "confound" explanation of results on the cognitive measures in the first two experiments. Furthermore, results on number of breakpoints marked and estimates of future performance were comparable to those obtained in the first two experiments.

One problem in these data, however, is that variance in number of units marked was much larger than in the previous two experiments. This difference may reflect the difference between the button-press procedure used in Experiment 1 and 2 and Wilder's (1978a) pencil-and-paper procedure in this experiment.

These data also support the interpretation that level of analysis alters the cessation of information integration. Subjects analyzing the ascending series into fine units predicted future performance to be poorer than subjects analyzing the series into larger units, and subjects analyzing the descending series into fine units predicted future performance to be better than subjects analyzing that series into large units. The precise relationship between estimates of future performance and number of units, it should be noted, will depend upon a number of factors and is not a simple linear function of number of units. These factors include the underlying pattern of performance, level of analysis, and time of termination of processing. In the present studies, for example, performance did not steadily increase or decrease; the pattern of performance was more on the order of a step function, with very good performance followed by very poor performance in the "descending" series and the reverse pattern in the "ascending" series. Nevertheless, one might expect a correlation between number of breakpoints and estimates of future performance in the fine-unit and slow-motion conditions, since the point of sufficiency should occur closer to the midpoint of the series when level of analysis was very fine. These correlations were computed for each sequence for the fine-unit and slow-motion conditions combined over the three experiments. For the ascending series, number of breakpoints correlated $-.27$ ($df = 37$, $p < .05$) with estimates of future performance, whereas this value was .64 ($df = 30$, $p < .001$) for the descending series. That is, when performance was poor at outset, finer unit analysis led to lower predictions of future performance; when performance was good at the outset, finer unit analysis led to higher predictions of future performance. Similar correlations over the larger unit conditions were not significant.

There was one result in Experiment 3 that was not consistent with the previous experiment. Despite the comparable number of units marked for the descending series in large-unit and fast-motion conditions, estimates of future performance and recall of percent correct tended to be significantly lower in the fast-motion conditions. It is possible that the novelty of the fast-motion presentation raised the criterion of sufficiency in this condition, although it is not clear why this was not equally the case for the ascending series.

General Discussion

Jones and Goethals (1971) identified three types of processes that can produce primacy effects: (a) discounting processes, whereby later information is rejected if it is inconsistent with earlier information; (b) assimilation processes, whereby the interpretation of later information is altered in light of previous information; and (c) attention decrements, whereby the perceiver's sample of information is biased in that it is largely drawn from the first part of the sequence.

The explanation of primacy effects that we

have proposed shares important features with each of these explanations. That is, once a point of sufficient information is reached, later information is rejected, consistent with a discounting interpretation, although this rejection is not seen as a result of its consistency with previous information. Jones and Goethals (1971) reject the discounting interpretation, noting that "it is difficult to see how the discounting hypothesis might apply in performance evaluation when there is no evidence for motivation decrement or variations in problem difficulty" (p. 38). Our suggestion would be that later evidence in a series may be "discounted," but only in the sense that it is not used, rather than being rejected.

Similarly, once a point of subjectively sufficient information is reached, both the "sufficiency" and assimilation interpretations make the same prediction. The assimilation hypothesis assumes that later information is distorted; the sufficiency hypothesis assumes it is disregarded. Thus the sufficiency explanation is proposed as an alternative view, but the present data cannot discriminate between them.

Finally, the sufficiency explanation incorporates some features of the attention decrement interpretation in that it postulates that such effects are due to a decrease in processing effort over time. The results of Experiment 3, as argued, rule out a simple attentional weighting interpretation of these effects.

One question raised by the present data is the reason that a "recency effect" was obtained in the fast-motion and large-unit conditions. That is, if subjects were maintaining an accurate count of successes, one might anticipate convergence of the large-unit conditions to an accurate estimate of a 50% success rate. This prediction, however, would require a number of assumptions as to the nature of processing that are, so far at least, unverified. One assumption would be that if successes were randomly arranged, estimates of success would be accurate. Jones et al. (1968) used randomly arranged sequences and found that estimates of future performance ranged as high as 61% in some series. A second assumption is that subjects do indeed keep running counts of total number of successes rather than more impressionistic estimates of success rates based on the last few observed outcomes. If the latter were the case, it should be noted, the judgment of success rate would simply reflect the estimate that was current when the point of sufficiency was reached.

Another question raised by these results concerns the relationship between level of analysis and information gain. Newtson (1973) argued that level of perceptual analysis determines potential information gain from observation. In the large-unit and fast-motion conditions of the present studies, more units were marked than there were outcomes in each of the conditions, so that all subjects should have had complete information on outcomes. The sufficiency explanation proposed here postulates that subjects reached their point of sufficiency because they picked up additional information as well.

Newtson (1973), in the initial study of level of analysis and information gain, found that observers analyzing a sequence into fine units of action had more confident and differentiated impressions of the actor. Subsequent investigations (cf. Deaux & Major, 1977; Newtson, 1976; Wilder, 1978b; Ebbesen, Cohen, & Lane, Note 1) have indicated that this effect may often be obtained for particular sequences, but sometimes is not found. No studies, to our knowledge, have reversed the effect such that greater information is gained under large-unit than under fine-unit analysis.

Newtson (1973) based his argument on an analysis of perceived actions in terms of information theory. Strictly defined in those terms, the notion that more units should provide greater *potential* information is a valid one. As Garner (1962) points out, however, there is a difference between the quantity of information that is potentially available in a series of instances and the information that is transmitted by those instances. That is, humans are able to use information only when it is available in particular forms or structures. Newtson's (1973) prediction that finer unit analysis should produce more information *gain* than large-unit analysis is like the prediction that concept attainment is a simple function of the number of instances presented.

Such a generalization in concept attainment paradigms is a highly limited one (cf. Bourne, 1966; Bruner, Goodnow, & Austin, 1956; Garner, 1962), restricted to sets of instances providing usable information in small increments. Newtson's (1973) prediction thus depends upon the further assumption that the actions discriminated provide information about the actor in a usable form. The present data further qualify this relationship. Level of analysis may be seen as setting the limits of information gain, but further processing of that information may depend upon other factors.

Reassertion and Giving Up: The Interactive Role of Self-Directed Attention and Outcome Expectancy

Charles S. Carver and Paul H. Blaney
University of Miami

Michael F. Scheier
Carnegie-Mellon University

Two experiments tested a theoretical model of behavioral self-regulation, which makes predictions about the effects of failure on a person's subsequent efforts. This model holds that degree of effort will be a product of two things: expectancy of being able to redress the failure and degree of self-attention. In the experiments, a failure pretreatment was used to create large within-self discrepancies among female subjects. It was predicted (a) that negative outcome expectancies regarding a subsequent task would lead to decreased persistence on that task, (b) that positive outcome expectancies for the subsequent task would lead to increased persistence on that task, and (c) that both of these tendencies would be mediated by self-directed attention. The results of the two studies supported these predictions. Discussion centers on implications for research and theory in the areas of self-awareness, self-efficacy, and helplessness.

A good deal of attention has been devoted in recent years to the consequences that an initial failure can have for subsequent task performances. Sometimes the inability to achieve an expected goal at one task has led to performance increments at a second task (e.g., Hanusa & Schulz, 1977; Roth & Kubal, 1975). This typically has been interpreted as reflecting heightened efforts to compensate for the prior inadequacy. In other circumstances, however, failure at one task has led to performance decrements at a second task (e.g., Hiroto & Seligman, 1975; Seligman, 1975). This "giving up" phenomenon is widely believed to reflect a belief that effort on the second task will not lead to a positive outcome.

The authors are grateful to Denise Brandom, Marcia Hamilton, Ileana Rodriguez, and particularly Jody Kreitchman, for their efforts in the collection of the data. The results of this research were presented in an abbreviated form at the 1979 meeting of the American Psychological Association, New York City.

Requests for reprints should be sent to Charles S. Carver, Department of Psychology, P.O. Box 248185, University of Miami, Coral Gables, Florida 33124.

A theoretical model of behavioral self-regulation has recently been proposed (Carver, 1979; Carver, Blaney, & Scheier, 1979) that has important implications for our understanding of performance increments and decrements as products of failure. This theoretical model was developed in a somewhat different context, however. Specifically, it was designed to describe the behavioral consequences of self-directed attention.

Self-Attention and Behavioral Regulation

Self-focused attention has been shown to have several predictable effects, two of which are directly relevant to present concerns. These two effects both occur when some behavioral standard has been made salient to the person prior to the heightening of self-focus. In such a case, self-directed attention is believed to cause the person to become more aware of his or her present state or behavior and how it compares to the standard. One frequently demonstrated consequence of this awareness is an enhanced tendency for self-attentive persons to alter their behavior so that it conforms more closely to the standard of comparison (e.g., Beaman, Klentz,

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3710-1859$00.75

Diener, & Svanum, 1979; Carver, 1974, 1975; Froming, in press; Scheier, Fenigstein, & Buss, 1974; Vallacher & Solodky, 1979). On the other hand, in at least one study (Duval, Wicklund, & Fine, 1972), persons in whom a large self versus standard discrepancy had been created simply withdrew more quickly from the experimental context when self-focus was high than when it was lower.

These two divergent effects of self-attention —enhanced conformity to behavioral standards, and withdrawal—are reconciled in the following way (Carver, 1979). When a discrepancy exists between a present state or behavior and a salient standard of comparison, self-focus leads initially to an impetus to match one's behavior to the standard. This is presumed to be the case until or unless something interrupts this impetus. Interruption can occur prior to initiating the attempts to alter one's behavior if, for example, the person knows ahead of time that reducing the discrepancy between self and standard will be difficult. Alternatively, interruption can occur during the discrepancy-reduction attempt itself. Any interruption of the discrepancy-reduction impetus leads to an assessment of outcome expectancy, that is, the perceived likelihood that the discrepancy can be reduced. This expectancy judgment repreents a kind of psychological watershed. Subsequent behavior can be seen as falling into one of two classes, depending on the outcome of this judgment. If the expectancy is favorable, the result is reassertion: further effort to reduce the discrepancy, to match one's behavior or state to the standard. This tendency should be exaggerated by further self-awareness. If the expectancy is unfavorable, the result is an impetus to withdraw. The execution of the withdrawal impetus should also be enhanced by further self-focus.

Carver et al. (1979) have applied this reasoning to analyzing the approach–withdrawal decision that may occur among fearful persons in response to their recognition of rising fear. Carver et al. tested subjects who were equivalent in their degree of self-rated fear of a specific stimulus but who differed from each other in their chronic expectancies of being able to approach and handle the feared stimulus. Experimentally enhanced self-attention led the doubtful subjects to withdraw at an earlier stage of the approach sequence than was true with less self-attention. On the other hand, self-attention tended to enhance approach among the more confident subjects, though not significantly so. These findings thus provided substantial support for the theoretical model, at least as it applies to fear-based behavior.

Failure, Expectancy, and Self-Attention

This theoretical model has a great many potential applications, however, of which the fear-response decision is only one. It also makes predictions, for example, about responses to failure. Failure produces a large discrepancy between one's present state and one's desired state (i.e., a discrepancy between oneself and the standard of comparison). According to our model, one's response to failure should be dictated in part by one's expectancy about being able to reduce this discrepancy. A positive expectancy—the perception that the gap can be closed successfully—should lead to reassertion attempts. This should be reflected by increased efforts to do well on a subsequent task. A negative expectancy—the perception that the discrepancy cannot be altered—should lead to an impetus to withdraw. This should be reflected by reduced efforts at a subsequent task. Moreover, both the reassertion and the withdrawal tendencies should be exaggerated by increased self-awareness.

Although there is some indirect support for this reasoning (McDonald, in press; Steenbarger & Aderman, in press), the model has not yet been tested directly in this type of behavioral context. To do so was the purpose of the present research. All participants in this research experienced a failure, which created a substantial discrepancy between their present states and their desired states. We then manipulated subjects' expectancies about whether or not they would be able to do well at a subsequent task. The subsequent task was chosen to provide us with a measure of subjects' persistence. It was predicted that subjects in whom positive expectancies had been created would display more persistence with high than with low self-attention. And

it was predicted that subjects in whom negative expectancies had been created would display less persistence with high than with low self-attention.

Experiment 1

Method

Subjects and Experimenters

Subjects were 74 female undergraduates from the University of Miami subject pool. We used only females in this experiment because our experimenters were female and we wished to avoid introducing the potential psychological complexity associated with mixed-sex dyads. Eight other subjects were deleted prior to data analysis, for the following reasons: 1 reported having succeeded on the initial (failure manipulation) task, 3 spontaneously reported the belief that neither task was possible, and 4 either failed to understand the instructions for the second task or else failed to follow those instructions, which resulted in their claiming to have solved an insoluble puzzle. Each subject, tested in an individual session, was randomly assigned to one of two expectancy conditions and to one of two self-attention conditions (described more fully below).

There were two experimenters; each interacted alone with the subject at a different stage of the experiment. The first experimenter was responsible for manipulating the subject's outcome expectancy but remained blind to the subject's self-awareness–condition assignment. The second experimenter was responsible for manipulating self-focus but remained blind to each subject's expectancy–condition assignment. Both experimenters were ignorant of the specific hypotheses being tested.

Procedure

The first experimenter escorted the subject to the first testing room. There she explained that the research team was evaluating a set of perceptual motor tasks for eventual use as an instrument for measuring abstract reasoning skills. It was stressed that the specific skills that these items assessed were very important in a number of professional and interpersonal domains. It was further explained that a wide variety of different test-item groups were being developed by the research team, in order to make possible measurement of these abilities from several quite different perspectives. The subject was led to believe that 12 different sets of items were being tested, although she herself would only be asked to work on 2 of the sets. Each participant in the project ostensibly was being assigned 2 randomly chosen item sets, in order to control for fatigue and order effects. In reality, all subjects were asked to attempt the same 2 tasks in the same order.

The experimenter continued by saying that some of the problem sets had been tested in previous semesters. In such cases, any information obtained from the previous research would be printed along with the instructions for that task. The experimenter concluded her preliminary remarks by saying that the subject would be asked occasionally to fill out some brief self-report scales. The subject was then given a questionnaire, which included an expectancy rating for the first task: "How well do you expect to do on your first task?" answered on a 9-point scale labeled *extremely poorly* at one end and *extremely well* at the other end.

Anagram task. Each subject then was given a sheet labeled "anagrams task." The sheet included printed instructions explaining that the task was to rearrange the letters of each item to form a word. Work space was provided, but the subject was cautioned not to guess randomly in the answer blanks, because a proportion of her incorrect answers would be subtracted from her total number of correct answers.

This sheet also included a paragraph indicating that the anagrams had been partially evaluated during three previous semesters. Scores on the anagrams task ostensibly had been found to predict scores on the "design problems" task and the "digit-symbol" task but not scores on the "mazes" task. This information was included to provide some validation in the subject's eyes for the expectancy manipulation that took place later (see below). This paragraph also indicated that University of Miami students over the previous three semesters had ostensibly averaged 7.21 correct solutions, with last semester's average being 7.34. This information was included in order to ensure that all subjects would view their own performances as failures. In actuality, the anagrams, chosen from Feather and Simon (1971) and Tresselt and Mayzner (1966), were quite difficult and in some cases impossible (overall, subjects' scores averaged .77, $SD = .93$).

The experimenter told the subject that she would have 5 minutes to work on the anagrams, "although I don't suppose you'll need all that time for just 9 items." The experimenter said she would be on the other side of the room working if the subject had any questions. After 5 minutes had elapsed, the experimenter indicated that the time was up and returned to where the subject was seated. She looked at the subject's performance with mild surprise and said, "That's not very good at all. Almost everyone gets at least five or so on this task." The experimenter then delivered the statement that constituted the manipulation of outcome expectancy.

Expectancy manipulation. In the positive expectancy condition, the experimenter continued as follows:

> What did I say was going to be your other task, the design problems? [After checking her list] Yes. Well, that's a good break for you. You see, the anagrams and design problems have both been

studied quite a bit already, so we know a lot about how they go together. The evidence so far is that the two are kind of opposites of each other. They both measure the same abilities, but in such different ways that people who do poorly on this one often seem to do much better on that one, and vice versa. Probably you'll be able to do better on the design problems.

In the negative expectancy condition, the experimenter said instead:

> What did I say was going to be your other task, the design problems? [After checking her list] Yes. Well, that's unfortunate for you. You see, the anagrams and the design problems have both been studied quite a bit already, so we know a lot about how they go together. The evidence so far suggests that the two correlate very very highly with each other, which means a person who does well on one will also do well on the other—if a person does badly on one, that person will do badly on the other one, too. So I'd expect you're not going to do very well on the design problems.

The experimenter went on to say that she was working only with the anagram task and that another person was handling the design problems in a different room. The experimenter said that the person supervising the design problems would deal with the subject from that point on, which would include seeing that the subject received credit for participation. The implication of the latter information was that the subject would have no further contact with the first experimenter.

The first experimenter then escorted the subject to a second experimental room, knocked on the door, introduced the subject to the second experimenter, and said that the subject was to work on the design problems next. The second experimenter guided the subject to a seat that faced the experimenter's desk and closed the door. She recorded on a form that the subject was undertaking the design problems as her second task, asked the subject what her first task had been, and recorded the subject's response. She then handed the subject a printed form that was labeled "instructions for design problems," and asked the subject to read these instructions carefully.

Design problem. The design problem used in the study was patterned after those developed by Feather (1961), which have been used a number of times subsequently to measure persistence (e.g., Glass & Singer, 1972). The goal of the task is to trace over all the lines of a geometric figure, according to two rules: first, the line must be continuous —the pen cannot be lifted from the page; second, whereas it is permissible to cross a line traced previously, each line segment must be traced once and only once. The instruction sheet included a simplified sample problem with illustrations of a correct solution and solution attempts that violated each of the two rules.

The instruction sheet continued by saying that the subject would be given four separate design problems. She was to work on the first one either until she solved it or until she decided to go on to the next one. Once she went ahead, she could not go back to prior puzzles. The subject was allowed to attempt to trace the design as many times as she wished (on separate pieces of tracing paper), provided that a previous attempt was discarded before a new attempt was begun (a wastebasket was provided for this purpose). It was implicit that neither the time taken to reach a solution nor the number of attempts required to reach a solution mattered in the scoring—only whether the problem was solved or not.

After briefly recapitulating the instructions, the second experimenter asked the subject to seat herself at a nearby table, on which were a felt-tipped pen and a stack of tracing paper. Also on the table were several pieces of nondescript equipment. The experimenter indicated that she herself was just going to keep working at her own desk while the subject worked at the design problems. The experimenter gestured at the clutter on the subject's desk, and said, "Don't pay any attention to this junk over here; it's part of another experiment." She then asked the subject to fill out a second self-report blank, which included a rating of how well the subject had done on her first task and a rating of how well the subject expected to do on the design problems (both on 9-point scales). The experimenter then placed the first design problem in front of the subject, saying, "Here's the first puzzle. By the way, this first one is the hardest one. Hardly anyone gets it, so don't be too surprised if you don't.[1] You can go ahead and start; just let me know when you want the next one."

The experimenter then turned and walked back to her own desk. As she did so, she unobtrusively looked at a clock on her desk, which had been shielded from the subject's view. Using that clock, she began timing the subject's attempt on the first design problem. In reality, the subject was given only one problem, for which there was no solution. The amount of time that the subject spent attempting that problem was the study's dependent variable.

Self-attention manipulation. Self-directed attention was varied during the second task by the presence or absence of a wall mirror (.75m × .50m) resting on the table at which the subject was working. (Evidence of the self-focusing properties of mirror presence is discussed in detail by Carver & Scheier, 1978.) In the mirror present condition, the mirror was situated directly in front of the subject's chair, leaning against the wall at an angle at which the subject could view her own reflection but not that of the experimenter. In the mirror

[1] This statement was included because pilot data had indicated that most subjects were highly persistent on the design problem in the absence of such a statement. This comment had the effect of reducing subjects' persistence slightly overall.

absent condition, the mirror's reflective surface was turned toward the wall. In both conditions, the mirror was implicitly included in the experimenter's reference to the "junk" that was part of another experiment. The instructions for the task had been given before seating the subject at the table so that there would be relatively little time for her to habituate to the mirror's presence before beginning the experimental task.

When the subject asked the experimenter for the second design problem, or after 10 minutes (whichever came sooner), the experimenter recorded the elapsed time, gave the subject a final brief questionnaire, and began to probe for signs of suspicion. She then took the subject to a third experimental room, where the general purpose of the study was explained. After being assured that her poor performances on the two tasks had been manipulated and were not her own fault, the subject was given credit for her participation and was dismissed.

Results

Manipulation Checks

It was important for an adequate test of our predictions that all subjects perceive a within-self discrepancy and that the positive and negative expectancy groups differ from each other in their expectancies of being able to reduce the discrepancy. To verify that this was the case, each subject was asked to complete two self-report items that served as checks on the failure and expectancy manipulations, respectively, just before beginning the design problems task.

The first item asked the subject to rate her performance on the first task (anagrams) by circling a number on a 9-point scale with endpoints labeled *very successful* and *very unsuccessful*. All subjects included in the data analysis circled numbers on the "unsuccessful" side of the neutral point (overall $M = 1.84$, $SD = 1.19$). Thus every subject viewed her performance on the first task as a failure. Just as important, a 2×2 factorial analysis of variance of subjects' responses to this item revealed that the experimental groups did not differ from each other in the degree to which they perceived the outcome of the first task as having been unsuccessful (all Fs < 1). Nor, in fact, had the groups differed reliably in actual performances on the anagrams task (Fs < 1.5) or in the expectations for success that they had expressed with regard to the anagrams task (Fs < 1).

On the other hand, subjects' ratings of how well they expected to do on the second task—the design problems—did differ reliably between expectancy conditions, $F(1, 70) = 5.45$, $p < .03$. Moreover, no effect other than this predicted main effect approached significance (other Fs < 1). Although the expectancy conditions differed from each other as had been anticipated, closer examination of the means revealed that the two expectancy manipulations had apparently not been equally effective. That is, the average rating among subjects in the negative expectancy condition was on the appropriate side of the neutral point of the scale ($M = 4.16$, $SD = 1.53$), but the average among subjects in the positive expectancy condition was almost exactly at the scale's neutral point ($M = 4.92$, $SD = 1.23$). We will return to this point below.

Persistence

The dependent measure of greatest interest was the amount of time that subjects had spent attempting to solve the design problem. An analysis of variance of these values (see Table 1) revealed a significant interaction between expectancy condition and self-awareness condition, $F(1, 70) = 4.87$, $p < .03$, as well as main effects approaching significance for both variables (ps $< .10$). Individual group comparisons revealed that all of these statistical effects depended primarily on the low persistence values among subjects who had been provided with poor outcome expectancies and for whom self-attention had been enhanced. These people withdrew from their attempts to solve the design problem more quickly than did either subjects with negative expectancies who were less self-attentive or subjects in whom self-attention had been enhanced but who had more positive expectancies, ps $< .05$ by Scheffé test. Contrary to our hypothesis, self-focus in the positive expectancy condition did not increase subjects' persistence. Nor, somewhat surprisingly, did negative outcome expectancy reliably reduce persistence in the absence of self-focus.[2]

[2] A separate analysis was also performed on the number of times the subject attempted to solve the problem, though prediction on that measure was

Table 1
Persistence (in minutes) at an Insoluble Task, as a Function of Outcome Expectancy and Self-Attention, Experiment 1

	Mirror absent			Mirror present		
Expectancy	Persistence	*SD*	*n*	Persistence	*SD*	*n*
Positive	8.15	2.38	17	8.43	2.20	19
Negative	8.51	1.88	17	6.55	2.21	21

Discussion

Experiment 1 provided clear evidence that self-focus enhances the tendency of subjects to withdraw from an experimental task when their outcome expectancies are negative. Self-directed attention did not cause withdrawal among subjects with more positive expectancies; however, neither did self-focus cause these subjects to display enhanced persistence on the second task as had been predicted.

There are several possible reasons for the failure to confirm this reassertion prediction. The most obvious possibility is that exaggerated persistence was prevented by our arbitrary imposition of a 10-minute time limit on the second task. The persistence means of three of the four groups were, in fact, relatively near this artificial "ceiling" on effort. Another possibility is suggested by the finding that subjects in the positive expectancy condition did not really have particularly positive expectancies. Although we can do little more at this stage than speculate as to where the expectancy "watershed" point actually is, it may be that these persons' outcome perceptions were not sufficiently positive to cause a discernible increase in reassertion under self-focus. A third possibility, of course, is that self-attention does not lead to reassertion under conditions of positive expectancy.

Because the reassertion prediction is an important part of our theoretical model, and because the results of at least one previous study (Carver et al., 1979) have been somewhat equivocal on the reassertion issue, we conducted a second experiment. In this second study an attempt was made to create slightly more positive expectancies in subjects, by means of slight changes in the expectancy manipulation. In addition, we minimized the effects of a potential ceiling on subjects' persistence by increasing the time limit. In Experiment 2, each subject was allowed up to 20 minutes to work on what she believed was the first of four design problems.

Experiment 2

Method

Subjects were 34 female undergraduates from the University of Miami subject pool. Two additional subjects were deleted prior to data analysis. One claimed to have solved the insoluble puzzle, and the other voiced suspicions about the experimental tasks.

All procedures in this study exactly duplicated those of the positive expectancy condition of Experiment 1, with two exceptions. First, the last portion of the positive expectancy manipulation was changed and expanded slightly, as follows: "They both measure the same ability, but in such different ways that people who do poorly on the anagrams often seem to do much better on the design problems, and vice versa. It seems funny, but almost always when people do badly on this one, they seem to do really well on that one. So from past experience I expect you'll do well on the design problems." The second procedural difference was that, as noted above, subjects were allowed up to 20 minutes to work on the "first" design problem. As in Experiment 1, subjects were randomly assigned to either the mirror present or the mirror absent condition.

Results and Discussion

As in Experiment 1, preliminary analyses revealed that the groups did not differ from

more ambiguous. That is, increased effort could result in more frequent attempts; alternatively, it could lead only to more concentration prior to making an attempt. Analysis of this measure yielded only a nonsignificant tendency toward more attempts in the mirror absent than the mirror present condition.

each other in first-task expectancies, number of anagrams solved ($M = .32$, $SD = .47$), ratings of their anagram performances ($M = 1.68$, $SD = 1.27$), or their expectancies with regard to the second task (all $Fs < 1$). (It may be noted that subjects' expectancies for the second task were slightly more positive overall than those of the comparable subjects in the first experiment, $M = 5.06$, $SD = 1.54$.)

Analysis of subjects' persistence on the second task revealed greater persistence among subjects in the mirror present condition ($M = 12.47$, $SD = 5.58$) than among subjects in the mirror absent condition ($M = 8.15$, $SD = 4.63$), $F(1, 32) = 6.04$, $p < .02$.[3] This difference proved to be even more reliable ($p < .008$) when a comparison between groups was made that included data from only those subjects who reported either neutral or positive second-task expectancies. Thus our hypothesis was confirmed. When one's outcome expectancy is positive, self-focus leads to enhanced efforts.

One final point should be made about these data. Subjects' persistence in the mirror absent condition of Experiment 2 was virtually identical to that displayed by the comparable subjects (positive expectancy – mirror absent) in Experiment 1. More to the point, neither of these values differed from the persistence displayed by subjects with negative expectancies in the mirror absent condition of Experiment 1. This absence of an expectancy effect in conditions of low self-focus is consistent with previous findings (Carver & Blaney, 1977a, Experiment 3; 1977b; Carver et al., 1979). Our explanation for this finding is straightforward. In the absence of an experimental manipulation, self-focus among our subjects may have been quite low. Our theoretical model describes effects that occur under conditions of relatively high self-attention. If self-focus were low enough, the postulated reassertion/withdrawal dichotomy would not have been evoked. Thus the absence of a main effect for expectancy does not appear to pose any problem for our theoretical analysis. Indeed, our data simply suggest that expectancy effects require some self-attention before they occur at all.

General Discussion

The research presented here conceptually replicates a previous finding (Carver et al., 1979), extending that finding in three important respects. First, Carver et al. *measured* outcome expectancy rather than *manipulating* it. Thus, although their results were consistent with the expectancy-based analysis, the findings were susceptible to the criticism that it could have been another variable, correlated with expectancy, that had really caused the effect. In the present research, in contrast, we experimentally manipulated outcome expectancy, thus minimizing that potential criticism.

A second way in which these findings add strength to those of Carver et al. (1979) concerns the degree to which reassertion can be said to have occurred when a positive expectancy was combined with self-directed attention. The previous study had found only directional support for that hypothesis (as was also the case in the present Experiment 1). Presumably this was because of a ceiling on subjects' efforts that was imposed by the nature of the task being attempted. In contrast, the present Experiment 2 clearly demonstrated such a reassertion response.

A third aspect of this replication may be most important of all. Specifically, we have demonstrated here that the same principles that allowed us in the past to predict fear-based behavior can be successfully applied to a fundamentally different behavioral domain. That is, the present predictions were based on precisely the same theoretical model and used exactly the same logic that led to the previous predictions of Carver et al. However, the logic in this case was applied not to the attempt to approach a feared stimulus, but rather to the persistence with which a person tries to reduce a within-self discrepancy caused by a prior failure. The fact that the theoretical analysis is so easily applied to these divergent areas of behavior suggests that the model may be very general indeed.

---

[3] Analysis of the numbers of times subjects attempted the problem indicated that there were marginally more attempts ($p < .08$) among mirror present than among mirror absent subjects.

There is one potential concern about these findings, however, which stems from the fact that a mirror was used to vary self-focus both in the present studies and in our previous one (Carver et al., 1979). Though we have argued elsewhere (Carver & Scheier, 1978; Carver & Scheier, Note 1) that the mirror is in many ways the "purest" way to increase self-attention experimentally, it does have one important side effect: It provides subjects with visual access to their facial expressions. With regard to the present research, this raises the possibility that subjects seated before a mirror became especially aware of their "hopefulness" (in the positive expectancy condition) or their "hopelessness" (in the negative expectancy condition) by observing their facial expression, inferred their internal states through this external mediation, and then behaved in a manner consistent with that inference (see, for example, Bem, 1972).

There are two sources of evidence against this line of reasoning: First, evidence converging on the validity of the self-attention construct has been gathered in a good deal of previous research (e.g., Carver & Scheier, 1978; Carver & Scheier, in press; Scheier & Carver, 1977; Scheier, Carver, & Gibbons, 1979; Scheier, Carver, & Gibbons, in press). The strategy in that research was to replicate mirror-induced effects using individual differences in the disposition to be self-attentive, which is termed self-consciousness (Fenigstein, Scheier, & Buss, 1975). Dispositional self-consciousness is a particularly useful tool for this purpose, in that its use appears to rule out possibilities such as external mediation of any obtained effects (see also Carver & Scheier, 1978; Scheier et al., 1979). That is, being a dispositional variable, it does not require the presence of any external stimulus to mediate its effects. By implication, this evidence suggests that mirror effects are also mediated by inward focus of attention.

The second source of evidence is a very recent study by Brockner (1979), examining a phenomenon that is conceptually similar to that studied here. Brockner was interested in the effects of self-focus on persons high and low in self-esteem, following success and failure experiences. He examined these effects by measuring dispositional self-consciousness as well as by manipulating mirror presence. Brockner found that in the absence of the mirror, dispositional self-consciousness led to precisely the same effects as had mirror presence. That is, among highly self-conscious subjects, failure led to a subsequent performance decrement for those with low self-esteem but not for those with high self-esteem. In contrast, persons who differed from each other in self-esteem, but who were low in self-consciousness, did not differ from each other behaviorally following failure. Brockner's results thus show an important convergence with the present data, which suggests in turn that the present effects were internally mediated.

Two differences between Brockner's research and our own should be noted briefly, both of which appear to add further generality to our theoretical stance. First, Brockner's research investigated the phenomenon of low self-esteem, rather than the giving-up response per se. The fact that his findings are predictable from our reasoning (see Brockner, 1979, for greater detail) provides one more indication that phenomena as diverse as anxiety, helplessness, and low self-esteem may have a common core of conceptually similar processes. A second point is that Brockner measured subjects' task performances, rather than persistence, on the test-phase task. Carver has argued elsewhere (1979) that when the situation does not allow behavioral withdrawal, a kind of *cognitive* withdrawal may occur, resulting in performance decrements. Brockner's data lend important support to that assertion.

Theoretical Implications

Three additional issues are raised by the nature of the variables from which we predicted subjects' behavior and by the nature of the behavior that we examined. These issues will be briefly addressed in the following paragraphs.

Self-awareness. The present findings quite obviously have some implications for theorizing about the behavioral consequences of self-directed attention. There is some division of opinion as to what these consequences are. Wicklund (1975a) has speculated that the prepotent response to self-focus is to attempt to

avoid it, either by withdrawing from the situation or by attempting to immerse one's attention in the environment (see also Wicklund, 1975b). In part, this is because Wicklund has viewed self-attention as an inherently aversive state, particularly when there is a large within-self discrepancy. To Wicklund, discrepancy reduction occurs only when self-focus cannot be avoided.

We, on the other hand, see self-focus as a necessary component process in the normal sequence of behavioral self-regulation (cf. Diener, 1979). From this perspective, we have argued that the prepotent response to self-directed attention is to attempt to reduce within-self discrepancies and that withdrawal occurs only if that attempt is interrupted, and even then only if self-assessment leads to a negative outcome expectancy (Carver, 1979; Carver et al., 1979). In our view, even when the discrepancy is very large, the reassertion impulse will hold sway if one's expectancy of being able to reduce the discrepancy is positive.

The results of the present research seem unequivocal in supporting our position over that of Wicklund. In order to provide a strong test of our reasoning, we designed the pretreatment phase of the present study so that large within-self discrepancies were produced among all subjects by a failure on the first task. Yet only when outcome expectancies were negative did self-focus lead to withdrawal. Subjects with positive expectancies exerted greater efforts in their attempts to do well on the second task when self-focus was high than when it was lower. It might be argued that our positive-expectancy subjects were simply immersing themselves in the second task to avoid self-focus (see Duval & Wicklund, 1972). This seems very unlikely, however, because an easier way of avoiding self-focus was readily available—asking for the subsequent puzzles, finishing them quickly, and leaving. (This was also the case in a study by McDonald, in press, cited earlier as providing indirect support for our model.) Moreover, if these subjects had been burying themselves in the experimental task in order to avoid self-focus, one must ask why subjects with negative expectancies did not similarly bury themselves in the task. In short, our explanation for the dichotomy of responses to self-focus is the most parsimonious presently available.

Self-efficacy. The present findings also appear to have implications for recent theorizing about "self-efficacy" and behavior regulation. There is a good deal of similarity between some of Bandura's (1977) ideas in that regard and aspects of our own reasoning, even though our analysis emphasizes moment-to-moment behavior regulation, whereas Bandura's emphasizes long-term differences as a function of therapy. It seems useful, therefore, to consider the implications of the present findings for the two models as they apply to persistence and giving up.

We have framed our discussion to this point in terms of "outcome" expectancies, following Carver's (1979) definition of outcome expectancy as the degree to which the person views a desired outcome as attainable. In our studies, however, we manipulated outcome expectancy largely by manipulating perceptions of efficacy expectancy.[4] Efficacy expectancy is viewed by Carver (1979) as one's self-perceived level of effectiveness in executing the needed responses, a perspective that is quite comparable to Bandura's, that is, "the conviction that one can successfully execute the behavior required to produce the outcomes" (1977, p. 193).

Although viewed in this light there are clear similarities between the models, the present data join those of Carver et al. (1979) in indicating the inadequacy of Bandura's theory in at least one important respect. Bandura's model fails to take into account the role of self-focus in the self-regulatory process. As is apparent from the present data, this is a role

[4] In Carver's (1979) terminology, outcome expectancy is held to depend on several variables, of which efficacy expectancy is only one. Others are such things as time constraints, environmental constraints, and knowledge of relevant response–outcome contingencies. Carver drew this distinction between these two types of expectancies because he believed that outcome expectancies are central in determining behavior (assertion vs. withdrawal), whereas efficacy expectancies determine the nature of concomitant affective experiences. Those predictions remain to be tested.

that should not be disregarded. That is, if we had not heightened self-focus among some of the subjects in the present research, we might have concluded that efficacy expectancies were not important in this behavioral context. Instead, we have shown that they are clearly important, though only in the presence of self-directed attention.

Helplessness. The present findings also seem to have some relevance for issues raised by researchers working in the "learned helplessness" tradition. All of our subjects received what might be construed as a helplessness pretreatment, and some of them displayed reduced persistence, which is often viewed as a sign of helplessness. For this reason, it is interesting to note some important similarities between our theory (and our findings) and the kind of cognitive analysis of helplessness in humans that recent theorists in that area have favored (e.g., Abramson, Seligman, & Teasdale, 1978; Hanusa & Schulz, 1977; Wortman & Brehm, 1975). We will then consider two differences between our model and previous theories.

Abramson et al. (1978), for example, have proposed a reformulation of helplessness theory in which the impact of a pretreatment on subsequent performance depends on one's beliefs about the relevance of one's pretreatment performance for performance on a subsequent task. In simpler terms, the effect of the pretreatment is mediated by its effect on the person's "expectation of future noncontingency." Expectation of future noncontingency is similar to what Wortman and Brehm (1975) called "expectancy of no control." Both, of course, are similar to what we have termed *unfavorable outcome expectancy.*

In the Abramson et al. model, this expectancy is influenced largely by the subject's attributions regarding the reasons for the initial failure.[5] Indeed, it is this attributional aspect of their model that has received by far the greatest amount of attention thus far. It is worth emphasizing, however, that despite this focus on attributions, it is the person's *expectancy* that ultimately influences performance, not the attributions themselves. The person who finds himself or herself expecting to do poorly, *for whatever reason,* should display "helplessness" effects. Persons who expect to do well should not show these effects.

The central importance of outcome expectancy in the Abramson et al. model is quite consistent with our own reasoning (Carver, 1979; Carver et al., 1979). However, our theory adds to theirs in two important respects. First, our model assumes that giving-up phenomena reflect an impulse to withdraw from the behavioral context. Indeed, both of the studies that have supported our analysis of giving up (Carver et al., 1979; the present Experiment 1) have used dependent measures embodying behavioral withdrawal as a response option. In contrast, in most studies in the helplessness tradition, such an option has not been explicitly available. As was mentioned above, Carver (1979) has suggested that when behavioral withdrawal is prevented, a cognitive withdrawal may occur, manifested either as a focus on one's inability to do the required behavior or as a mental dissociation from the task, in which further attempts are sporadic or halfhearted. Thus, in our view, the kinds of deficits shown in helplessness studies may actually depend on an impulse to remove oneself, physically or cognitively, from the behavioral context.

It is interesting to note, in this regard, that there is indirect support for this notion from at least one previous research project in the helplessness area (Diener & Dweck, 1978). Diener and Dweck studied the verbalizations and behaviors of children, classified either as

[5] Previous research has shown that exposure to a mirror can increase the amount of causality attributed to the self for hypothetical outcomes (Duval & Wicklund, 1973; Buss & Scheier, 1976). Inasmuch as the internal–external attributional dimension plays an important role in the model of Abramson et al. (1978), it might appear that their model thus is capable of explaining the persistence differences between self-awareness conditions obtained in the present research. This does not, however, appear to be the case. The Abramson et al. model seems to suggest that attributional internality will affect only the person's level of self-esteem following failure, not the extent to which persistence occurs on subsequent tasks. Thus, any explanation involving attributional internality would seem to be inadequate to account for the present findings.

"helpless" or "mastery-oriented," who were confronted with a series of task failures. The response style of mastery-oriented children included the following: monitoring of their own behaviors; verbalization of task-oriented self-instructions; attempts to renew their concentration; statements of positive affect ("I love a challenge"); and statements reflecting a positive prognosis ("I've almost got it now"). Helpless children did not make statements reflecting monitoring of their behavior or self-instructions but were much more likely to make statements of negative affect ("This isn't fun anymore") and statements that were irrelevant to task solution ("There is a talent show this weekend, and I'm going to be Shirley Temple"). Diener and Dweck characterized the latter category of statements as reflecting psychological withdrawal from the situation, which implicitly was not physically escapable. This characterization is quite consistent with our reasoning.

The second inadequacy of the Abramson et al. model is, of course, the same as the one discussed above regarding Bandura's (1977) analysis of fear-based behavior. Specifically, it has no mechanism for taking into account the effect of self-attention. Accordingly, it is unable to account for the present pattern of results. In supporting our theoretical model (Carver, 1979; Carver et al., 1979), the present findings thus suggest that the deficits obtained in helplessness research may be due in part to a process not yet addressed by helplessness theorists: the focusing of attention on oneself.

Consistency and Bias in the Attribution of Attitudes

Icek Ajzen, Carol Ann Dalto, and Daniel P. Blyth
University of Massachusetts—Amherst

This article is based on the proposition that people attribute a disposition to an actor by evaluating its consistency with other information about the actor or the situation. This strategy is assumed to be accompanied by a cognitive set or bias to view ambiguous information as consistent with the hypothesized disposition. Respondents were told that a student had chosen or had been assigned to write a proabortion or antiabortion paper, and they were or were not given an ambiguous description of the author's personality. In support of predictions, under choice conditions attitudes were always attributed in accordance with the paper's position, but under assignment conditions such attributions occurred only when respondents received the ambiguous personality description.

A central focus of attribution theory is the tent to which an actor's behavior provides formation about his or her stable underlying spositions (cf. Ajzen, 1971; Jones & Davis, 965; Steiner, 1970). Most analyses of the tribution process (e.g., Heider, 1958; Jones Davis, 1965; Kelley, 1967) have likened servers to naive scientists who, except for a w motivational biases, make systematic use the information available to them. It has cently been suggested, however, that instead using sophisticated information-processing rategies, people rely on rather simple intuive heuristics (Tversky and Kahneman, 974) or cognitive scripts (Abelson, 1976) in aking their judgments (see Slovic, Fischhoff, Lichtenstein, 1977, for a review). Although ese intuitive strategies often produce reanable judgments, they are said to be capable leading to systematic biases and errors Ajzen, 1977; Kahneman & Tversky, 1973; isbett & Borgida, 1975).

This article deals with what Ross (1977) s termed the *fundamental attribution error,* e assumed tendency for observers to overtimate the importance of dispositional factors relative to environmental factors. We will try to identify a cognitive strategy that may be in part responsible for any such bias and to specify some of the conditions under which this bias is likely to materialize.

One area in which the fundamental attribution error is assumed to operate is the attribution of attitudes on the basis of observed (or reported) behavior. Jones and Harris (1967) reported that observers attribute attitudes to the author of an essay in accordance with the position advocated in the essay. Although weaker, this tendency also emerged under conditions in which situational constraints, in the form of an assigned position on the issue, appeared sufficient to explain the actor's behavior. This and other studies along the same lines (e.g., Jones, Worchel, Goethals, & Grumet, 1971; Miller, 1976; Miller, Mayerson, Pogue, & Whitehouse, 1977; Snyder & Jones, 1974) are usually taken as evidence for a pervasive bias on the part of observers to attribute an actor's behavior to internal dispositions rather than to environmental factors.

Note, however, that even under conditions of little choice, attribution of behavior to internal factors does not necessarily imply a bias in favor of dispositional explanations. The presence of a viable situational cause (such as assignment by a course instructor) should produce some discounting of the dis-

The authors thank Ronnie Bulman for her comnts on an earlier draft of this paper.

positional explanation (Kelley, 1973), but it need not completely discredit it. We might thus reasonably expect that under situational constraints, the position expressed in an essay would have a significant, though weaker, effect on the author's perceived attitude.

Before considering potential biases, we must explore the cognitive strategies people employ when asked to judge the likelihood that the author of an essay actually holds an attitude in accordance with the expressed position. This article is based on the proposition that in attributing an attitude or any other disposition to an actor, observers evaluate the extent to which the disposition in question would be consistent with other available information. A similar strategy has been suggested by Ajzen and Fishbein (1975) in their application of Bayes' theorem to causal attribution, and by Kruglanski, Hamel, Maides, and Schwartz (1978) in their analysis of lay epistemology.

Evaluation of consistency in the validation of specific hypotheses concerning an actor's dispositions can be described as follows. When judging the validity of a given dispositional attribution, the observer examines the extent to which the stipulated disposition is consistent with other information about the actor and about the context in which the behavior occurred. The greater the number of informational items consistent with the disposition, the more confident the observer will be that the actor in fact has the disposition in question. Information inconsistent with the stipulated disposition should lower the observer's confidence.[1]

The interpretation of information as consistent or inconsistent with a given disposition is, however, not made in a vacuum. It is here proposed that these judgments are influenced, among other things, by prior beliefs concerning the validity of the hypothesized disposition. Once a person has formed a given dispositional hypothesis, he or she will tend to interpret new information as consistent with the disposition in question. A prior hypothesis is thus assumed to provide a "cognitive set" for the processing of new information. As is true of a perceptual set, this tendency to view new information as consistent with a prior hypothesis should be particularly pronounce in the case of ambiguous information that is and of itself has little bearing on the validity of the hypothesis under consideration. Th end result of such a tendency would be a overestimation of the amount of evidence sup porting the hypothesis, in this instance th disposition that is being attributed.

A bias toward perceiving ambiguous infor mation as consistent with prior hypothese could help explain attribution of attitude under situational constraints. In previou studies, subjects were given a considerabl amount of information that may have bee interpreted as consistent with the hypoth esized attitude. For example, in their first ex periment, Jones and Harris (1967) describe the author of the essay as "a student at th University of North Carolina, a resident o the state, and the son of an automobile sales man." Furthermore, the respondents read th 200-word essay defending or criticizing Ca tro's Cuba. The direction of the essay pro vided the initial dispositional hypothesis. Th description of the author and the style an organization of the material in the essay, bo ing largely ambiguous with respect to the di positional hypothesis in question, may hav been interpreted as consistent with the infe ence that the author's attitude correspond to his expressed position in favor of or again Castro's Cuba. Providing ambiguous back ground information may thus have attenuate any tendency to discount the disposition hypothesis under conditions of situation constraints.

One implication of this analysis is that the ambiguous background information we removed, apparent support for the hypoth esized disposition would be greatly reduced eliminated, thus resulting in little dispos tional attribution under no choice condition The study reported below was designed part to test this prediction. In addition, it a tempted to provide a more direct test of th operation of the cognitive set assumed t accompany use of the consistency strateg

[1] The person is also assumed to take into accou each item's diagnosticity or informational value f the disposition under consideration.

Information known to be ambiguous with respect to the attribution in question was provided for some subjects. This information, in the form of a general personality description, was assumed to permit emergence of the consistency bias and hence to increase dispositional attributions in the presence of situational constraints.

Method

Subjects

A total of 256 male and female[2] undergraduate psychology students received experimental credit for their participation in the study. They were assigned at random and in equal numbers to the 12 experimental and 4 control conditions (16 per cell).

Procedure

The participants were scheduled in small groups and were handed a self-contained questionnaire that described the experiment as a study of the perception and interpretation of social events. They then read about a student who had written a paper in favor of or against abortion. The stand taken on the issue either had been assigned to the student or had been a matter for his or her choice. For one-third of the participants, the freedom-of-choice information was followed by an ambiguous description of the student's personality. The order of presentation was reversed for another third of the participants. Here, the personality description appeared prior to the choice information. The remaining participants received no information about the student's personality. Specifically, the two conditions containing personality descriptions provided the following information.

> Peter G. is a student at Hampshire College. Last semester he wrote a paper for a social science class in which he took a stand favoring [opposing] abortion on demand. The course instructor had given the following instructions for the paper.
>
> *Free choice condition.* Based on the past week's readings and lectures, write a short essay either defending or criticizing abortion on demand.
>
> *No choice condition.* Based on the past week's readings and lectures, write a short essay defending [criticizing] abortion on demand.

The personality description appeared either prior to or after this choice manipulation.

> The following paragraph gives you a short description of Peter's personality. It was prepared by a psychologist on the basis of a personality inventory administered to all students in the class.
>
> Peter G. prides himself as being an independent thinker and he does not accept others' opinions without satisfactory proof. He has a great deal of unused capacity that he has not turned to his advantage. Peter has a tendency to be critical of himself. He has a strong need for other people to like and admire him. At times he has serious doubts as to whether he has made the right decision or done the right thing. Disciplined and controlled on the outside, he tends to be worrisome and insecure on the inside. Some of his aspirations tend to be quite unrealistic. Peter has found it unwise to be too frank in revealing himself to others. He prefers a certain amount of change and variety and becomes dissatisfied when hemmed in by restrictions and limitations. While he has some personality weaknesses, he is generally able to compensate for them.

This description contains 10 of the 12 statements used previously by Ulrich, Stachnik, and Stainton (1963), who showed that students readily accept such general statements as accurate descriptions of their personalities (see also Carrier, 1963; Forer, 1949).

At this point (or immediately after the choice information in the no personality conditions), attribution of attitude was assessed. "What do you think is Peter G.'s true position on the question of abortion on demand? The probability that Peter G. favors (opposes) abortion on demand is _____%."

To test our assumption that the personality description was ambiguous or neutral with respect to this judgment, control subjects were given no information about the stand Peter G. had taken on the issue of abortion or about his freedom of choice. They were simply told that he had written a paper for a social science class concerning the issue of abortion on demand, and one-half of the control subjects were given the description of Peter G.'s personality. On the basis of this information, they were asked to judge the probability that Peter G. favored (or opposed) abortion on demand.

Results

Ambiguity of Personality Description

A 2 × 2 analysis of variance was performed on the control data. The factors in this analysis were personality description (yes or no) and question format (in favor of or opposed to abortion). Responses were scored, with high numbers indicating a proabortion stand. That is, when subjects judged the probability that Peter G. was opposed to abortion, their responses were subtracted from 100. Neither

[2] Since there were no significant differences between males and females, the participants' sex will not be further considered.

Table 1
Mean Estimates of Proabortion Attitudes Under Different Experimental Conditions

Direction of essay	No personality description		Personality description	
	Choice	No choice	Choice	No choice
Pro-abortion	80.44	57.19	68.50	63.59
Anti-abortion	20.94	50.00	35.68	44.47

Note. $n = 16$ per cell in the no personality conditions and $n = 32$ per cell in the personality conditions.

the main effects nor the interaction were statistically significant ($F < 1.0$ in each case). Disregarding question format, the mean probability of a proabortion attitude was judged to be 57% when the personality description was provided and 59.5% without the personality description. Clearly, then, in and of itself the personality description had no appreciable effect on attitude attributions.

Attribution of Attitudes

The data of the experimental conditions were submitted to a 2 × 2 × 3 analysis of variance, with direction of essay (pro vs. con), freedom of choice (choice vs. no choice), and personality description (before choice information vs. after choice information vs. no personality description) as design factors. Since there were no significant differences due to the positioning of the personality description (before or after the choice information), the data for these two conditions were pooled, resulting in a 2 × 2 × 2 design. For ease of presentation, the data are discussed only in terms of this latter design.

Table 1 presents mean probability judgments, scored with high numbers again indicating attributions of proabortion attitudes. Table 2 shows the results of the analysis of variance. The significant main effect for direction of essay indicates that, predictably, a student who wrote a proabortion essay was viewed as more likely to be in favor of abortion than a student who wrote an antiabortion essay. More interesting, the significant interaction between essay direction and fre dom of choice shows that this effect w stronger in the choice condition than in t no choice condition.

Most important, however, is the significa three-way interaction. It indicates that t presence or absence of an ambiguous pe sonality description influenced the extent which the effect of essay direction was co tingent upon freedom of choice. The patte of means shown in Table 1 supports our h potheses. Consider first the results obtain when no personality description was provide It can be seen that as in previous studi essay direction had a strong effect on attri uted attitudes under free choice condition Contrary to previous findings, however, the was virtually no difference due to direction the essays under no choice conditions. Po hoc comparisons revealed that the effect d to direction of essay was significantly grea for choice than for no choice subjects, $F($ 184) = 20.97, $p < .001$. Moreover, the di ference between 57.19 and 50.00 in the n choice condition was not statistically signi icant ($F = 1.21$).

Very different results emerged when t participants were given the ambiguous d scription of Peter G.'s personality. Here, su jects attributed attitudes in accordance wi the position expressed in the essay even in t presence of situational constraints. Essay d rection had a significant effect on attributio under choice conditions, $F(1, 184) = 25.2$ $p < .001$, by post hoc comparison, as well under no choice conditions, $F(1, 184) = 8.$ $p < .005$. Further, the effects due to the

Table 2

* $p < .001$.

rection of the essays (proabortion or antiabortion) did not differ significantly under the two freedom-of-choice conditions ($F = 2.20$).

Post hoc comparisons also revealed that the ambiguous personality description *reduced* the effect of essay direction in the free choice situation. The difference between proabortion and antiabortion essays, given a personality description ($M = 32.82$), was significantly smaller, $F(1, 184) = 8.34$, $p < .005$, than the difference between these essays when no personality description was provided ($M = 59.50$).

Discussion

The findings reported in this article are consistent with our analysis of dispositional attribution. When no personality description of the essay's author was made available, respondents' judgments were strongly influenced by the presence or absence of situational constraints. Attitudes in accordance with the position advocated in the essay were attributed to authors who were free to support or oppose abortion on demand, while respondents were uncertain as to the attitude of an author who had written his essay under no choice conditions. In fact, given situational constraints and no personality description, dispositional attributions were very close to those made by control subjects who were given no information about the position advocated in the essay. These results provide little support for the argument that observers have a pervasive tendency to attribute an actor's behavior to internal dispositions. When situational constraints are salient and no other information is available, there seems to be no inclination to make dispositional attributions.

However, the availability of other information in the form of an ambiguous description of the actor's personality had a profound effect on dispositional attributions. Even though by itself the description was found to be completely uninformative with respect to attitudes toward abortion, it increased dispositional attributions in the no choice conditions. At the same time it was found to weaken such attributions in the choice conditions. Only the former effect was predicted, but both effects may in retrospect be viewed as reflecting the same underlying process. When no personality description was provided, all information available to the respondent was either consistent with the hypothesized disposition (in the choice conditions) or largely discredited by situational constraints (in the no choice conditions). As a result, freedom of choice had a strong effect on attribution of attitudes.

In contrast, even given the operation of a cognitive set to interpret ambiguous information as consistent with the hypothesized attitude, some of the information contained in the personality description is likely to have been viewed as contradicting the dispositional attribution. Taken as a whole, the available information would still favor attribution of an attitude corresponding to the behavior, but the few items of contradictory evidence would tend to lower confidence in the attribution. The situational constraints in the no choice conditions would again act to discredit the behavioral information and thus to some extent further reduce the strength of the dispositional attributions. Consequently, freedom of choice was found to have an effect on attribution of attitudes, but its effect was not significant and was much less pronounced than in the conditions where no personality description was provided.

This finding appears to contradict previous research (e.g., Jones & Harris, 1967), which has reported significant interactions between essay direction and freedom of choice. Note, however, that although previous research also provided some ambiguous background information, the personality conditions of the present study contained a much more elaborate set of such information explicitly designed to be interpretable as consistent with a proabortion or antiabortion attitude. As a result, only a little discounting of the dispositional hypothesis was found to occur under no choice conditions when the personality description was provided.

The tendency revealed in the present study to view ambiguous information as consistent with a prior hypothesis could theoretically function in different ways. One possibility is

that a dispositional attribution in accordance with the essay's position becomes anchored in the personality description, and as a result subsequent refutational evidence (in the form of information about situational constraints) is rendered relatively ineffective (cf. Ross, 1977). This account was not supported by the present study, since providing the personality description had the same effect whether it appeared prior to or after the freedom-of-choice information. Instead, information about the essay appears to have led respondents to hypothesize a corresponding disposition, and evidence consistent with this hypothesis was then sought in other available information. The cognitive set created by such an orientation seems to produce a tendency to interpret ambiguous information as consistent with the hypothesis in question.

On the Requirements of Proof: The Timing of Judicial Instruction and Mock Juror Verdicts

Saul M. Kassin and Lawrence S. Wrightsman
University of Kansas

At the close of a trial, the judge instructs the jury that the defendant is presumed innocent, that the burden of proof is on the prosecution, and that guilt must be established beyond a reasonable doubt. In view of criticisms that the judge's charge has no effect on jury decisions, the present study examined whether the timing of judicial instruction mediates its efficacy. One hundred seven mock jurors watched a 1-hour videotape of a trial and were instructed by the judge either before the evidence, after the evidence, or not at all. Results for posttrial measures indicated that although the timing manipulation had no significant effect on the standards of reasonable doubt adopted by subjects, those who were instructed before the evidence viewed the defendant as less likely to have committed the crime and demonstrated a lower conviction rate than subjects in the instructions-after and no-instructions groups. Results for a series of mid-trial judgments of 54 subjects further indicated that pre-instructed subjects were less likely to convict throughout the trial. These findings are discussed, and their implications for procedural reform in the courtroom are noted.

In trials by jury, the judge is obligated to instruct jurors in both general and case-specific matters of law. These instructions serve a number of functions: The judge orients jurors in their task, outlines the undisputed facts and issues of the case, explains the relevant law, and informs jurors about procedural matters (McBride, 1969). From the defendant's perspective, perhaps the most crucial of the mandatory instructions is that concerning the "requirements of proof" (LaBuy, 1963). Specifically, the accused is entitled to the instruction that he or she is presumed innocent, that the burden of proof is on the prosecution, and that all elements of the crime must be proven to a constitutional standard of "beyond a reasonable doubt."

Although the potential importance of the judge's charge is widely recognized (McCart, 1964), its actual effectiveness is a subject of controversy. On the one hand, the courts assume that jurors understand their instructions, use them in making decisions, and are acutely sensitive to even minor variations in wording. Thus, attorneys often request specific instructions, appellate courts have occasionally reversed verdicts on the basis of an improperly worded instruction, and many states currently favor the practice of having judges recite a preapproved pattern instruction in order to ensure standardization. Experimental support for the effect of variations in instructional content has recently been obtained. Kerr et al. (1976) presented mock jurors with one of three definitions of reasonable doubt: one that described a lax criterion of reasonableness (i.e., "you need not be absolutely sure that the defendant is guilty to find him guilty," p. 286), one that described an extremely stringent criterion (i.e., "if you are not sure and certain of his guilt, you must

find him not guilty," p. 286), and one in which reasonable doubt was not defined. As it turned out, these varying definitions significantly influenced both individual and group verdicts—a lax criterion resulted in a high conviction rate, whereas a stringent one produced a low rate of conviction. Subjects for whom reasonable doubt was not explicated fell between these extremes. This study thus demonstrated that verdicts are indeed influenced by the reasonable doubt element of the requirements-of-proof instruction.

On the other hand, it has been suggested by legal scholars (Frank, 1949) and researchers (Sealy & Cornish, 1973) that these instructions have little effect on jurors' verdicts. One common criticism is that because they are written in statutory language, the instructions are often confusing to laypersons untrained in the law (Elwork, Sales, & Alfini, 1977). In fact, one study revealed that 40% of 375 sampled jurors reported that they did not understand their judge's instruction (Hervey, 1947). A second criticism is aimed at the timing of the judge's charge. Although the procedure is not fixed by law, the jury is typically instructed at the close of the trial presentation, that is, after the evidence has been presented. Although it is possible that this sequence increases the salience of the instruction and its availability for recall during deliberation,[1] a number of sources (e.g., McBride, 1969) have questioned the utility of an instruction that is given at a stage where jurors might have already decided on a verdict. Kalven and Zeisel (1966) noted that jurors often form very definite opinions about a defendant's guilt or innocence before the close of the trial. Accordingly, Judge E. Barrett Prettyman (1960) argued the following:

> It makes no sense to have a juror listen to days of testimony only then to be told that he and his conferees are the sole judges of the facts, that the accused is presumed to be innocent, that the government must prove guilt beyond a reasonable doubt, etc. What manner of mind can go back over a stream of conflicting statements and alleged facts, recall the intonations, the demeanor, or even the existence of the witnesses, and retrospectively fit all these recollections into a pattern of evaluation and judgment given him for the first time after the events; the human mind cannot do so. . . . Why should not the judge, when the jury is sworn, then and there tell them the rules of the game. (p. 1066)

In view of the flexibility in courtroom procedure and the potential importance of the judge's charge to the jury, the absence of research on temporal factors associated with the instructions is surprising (Elwork, Sales, & Alfini, 1977, is an exception). After all, order effects in the perception of unfolding behavior sequences have repeatedly been noted in both person perception (Jones et al., 1968) and jury contexts (Walker, Thibaut, & Andreoli, 1972). In the latter study, Walker et al. (1972) varied the order in which the prosecution and defense presented their cases but did not address the issue of judicial instruction.

The present study was designed to investigate the relationship between the timing of the judge's instructions and mock juror verdicts for a criminal case. In particular, the aims of the research were twofold. First, we sought to determine whether or not a prototypical, ecologically valid instruction on the requirements of proof influences jurors' decisions and whether the timing of that instruction mediates its efficacy. In order to achieve these goals, requirements-of-proof instructions were gleaned from those currently employed (De Vitt & Blackmar, 1977; LaBuy, 1963; McBride, 1969) and were introduced to subjects before testimony, after testimony, or not at all. At the conclusion of the trial presentation, subjects rendered their individual verdicts and answered a number of other case-related questions. Since the requirements of proof are defendant oriented, their effectiveness should be manifested in a lowered rate of conviction. Based on jurors' tendencies to make early decisions about guilt or innocence and Judge Prettyman's (1960) reasoning that instructions can have their intended effects only when they are delivered before jurors have made up their minds, a kind of primacy or inoculation effect was predicted. That is, the present instructions should produce fewer guilty verdicts when presented before the evidence than when presented after it.

The second general aim of the present study was to explore the mechanism or cog-

[1] Jones and Goethals (1971) have termed this the "recall readiness" hypothesis for recency effects.

nitive process that underlies the proposed order effect. Requirements-of-proof instructions may operate either by decreasing the belief that the defendant committed the crime (i.e., a lowered probability-of-commission estimate) or by increasing the standard or threshold to which that likelihood is compared (i.e., a stringent interpretation of reasonable doubt). Consequently, both were assessed. A collateral issue addressed here was whether or not subjects who are instructed prior to the presentation of evidence evaluate evidentiary information differently as it unfolds from those who do not receive prior instruction. Accordingly, half the subjects in each instruction group made judgments of guilt–innocence at various points during the trial. It was hypothesized that instructed subjects would set a higher standard by which to evaluate the case against the defendant and would therefore be less influenced by the prosecutor's case throughout the trial.

Method

Subjects and Design

A total of 107 introductory psychology students (47 male, 60 female) participated in the study. The experiment was conducted in 25 small groups ranging in size from 3 to 7 and took 1 hour and 20 minutes to complete. Each group was randomly assigned to one of six cells produced by the 3 (Judge's Instructions Before Evidence, Instructions After Evidence, No Instructions) × 2 (Multiple Judgments vs. Single Judgment Only) factorial design.

Procedure

Upon entering, subjects were told that they would observe a videotaped trial simulation, after which they would be asked to render a verdict. They were further instructed that as jurors they should be attentive but should not take notes and should not converse while the trial presentation was in progress.

All subjects were then told that in order to get the entire trial presentation on one reel of tape, a few pauses and meaningless exchanges had been deleted, but that all the testimony remained intact. Those groups who were to receive the judge's instruction, however, were informed that this instruction had inadvertently been deleted but would be read to them at the appropriate time from the original transcript. Finally, subjects in the multiple-judgment cells were informed of the fact that at certain points the tape would be stopped and their judgments would be assessed. The trial was then presented.

The Trial

The stimulus trial was one that had previously been employed (Juhnke et al., 1979). Stylistically, the simulation was presented on a 1-hour (black and white) videotape in which a number of law students retried a case in a realistic courtroom setting. It was filmed from a juror's perspective: the judge, attorneys, and witness stand were all in view.

Substantively, the trial was based on an actual criminal case in which the defendant, Ronald Oliver, was charged with stealing a car and with transporting it across state lines.[2] Though continuously presented, the trial consisted of the following three distinct phases: (a) opening statements by prosecutor and defense; (b) direct examination, cross-examination, and redirect examination of two prosecution witnesses (the salesman from whom the vehicle was stolen and the arresting officer) and one defense witness (the defendant); and (c) closing arguments of counsel (prosecution, defense, prosecution). The judge's instructions on the requirements of proof represented a fourth phase whose presence–absence and timing were varied.

In one condition, these instructions appeared prior to the introduction of evidence (i.e., between the first and second phases). In a second condition, they appeared after the closing arguments (i.e., after the third phase). In a third condition, no instruction was given. The specific instruction employed was neither strong nor weak. Rather, it was patterned after the approved instructions designed to convey each element of the requirements of proof: presumption of innocence, burden of proof, and reasonable doubt (see DeVitt & Blackmar, 1977; McBride, 1969). The instruction read as follows:

> Ladies and gentlemen of the jury—at this point I want to emphasize that the law presumes the defendant, Ronald Oliver, to be innocent unless proven otherwise. A defendant begins the trial with a "clean slate" with no evidence against him.
>
> This presumption places the burden *not* upon the defendant to prove his innocence but, on the contrary, the burden is on the prosecution to convince you beyond any reasonable doubt that the defendant, Ronald Oliver, committed the crime. That burden never shifts at any stage of the proceeding to the defendant. Ronald Oliver has no obligations of any kind to go forward and prove that he is innocent.
>
> You have now heard the term "reasonable doubt."

---

[2] A transcript taken verbatim from the videotape and a summary of the trial are available upon request.

Table 1
Pattern of Final Verdicts in Each of the Six Cells

Instruction and verdict	Multiple judgments		Single judgments	
	No.	%	No.	%
Before				
Guilty	7	39	6	35
Not guilty	11	61	11	65
After				
Guilty	12	63	10	56
Not guilty	7	37	8	44
None				
Guilty	12	71	10	56
Not guilty	5	29	8	44

What is it? It is a doubt based upon reason and common sense—the kind of doubt that would make a reasonable person hesitate to act in important matters. To summarize, the defendant is presumed innocent, so the prosecution must prove to your satisfaction beyond any reasonable doubt that Ronald Oliver is guilty. If two conclusions can reasonably be drawn from the evidence—one of innocence and one of guilt—the jury should adopt the one of innocence.

Dependent Measures

At the close of the trial, all subjects responded individually and without deliberation to a two-page questionnaire in which they first rendered a dichotomous judgment (guilty–not guilty) and indicated their confidence in that verdict on a 0–8-point scale. They then rated the strength of the evidence as well as their interest and involvement in the case (all on 0–8-point scales).

Since verdicts are a function of the perceived probability that the defendant committed the crime and of the standard of proof deemed necessary for conviction, both of these variables were also assessed. All subjects were thus asked, "What is the likelihood that the defendant committed the crime?" to which they responded by circling a number from 0 to 100 (in multiples of 5), and "A defendant should be found guilty if there is at least a _____% chance that he committed the crime." Finally, subjects answered 16 short-answer recall questions that pertained to the major facts of the case (e.g., "On what highway was Ron Oliver stopped?"). The total number of correctly recalled items served as a measure of fact recall.

In addition to providing these outcome data, half the subjects indicated their judgments (guilty–not guilty), confidence values, and probability-of-commission estimates at six distinct points during the trial—after both the direct examination and cross-examination of each witness. Specifically, they were asked, "If the trial ended now, would you vo that the defendant is *guilty* or *not guilty*?" "Ho confident are you in this judgment?" (0–8) "Wh is the likelihood that the defendant committed t crime?" (0–100). It was thus possible to trace b liefs as the trial unfolded and to examine wheth subjects who were already instructed on the r quirements of proof (instructions before) evaluat the evidence differently from those who had n yet been instructed (instructions after and no i structions). Previous research employing the multiple judgments (e.g., Weld & Danzig, 1940) h been criticized on the ground that such a pro cedure may bias final verdicts (Davis, Bray, Holt, 1977). For that reason, only half the sub jects in the present study made these on-li responses. A comparison of their posttrial respons with those of single-judgment subjects thus pro vided a test for the (non)reactivity of the pro cedure.

Results

Outcome Measures

Overall, 53% of the subjects voted guilt and 47% voted not guilty. The pattern o verdicts in each cell appears in Table 1.

In order to test for all main and interac tion effects and to determine which model best fits these categorical data, these dichoto mous judgments were analyzed with a likeli hood ratio (goodness of fit) chi-square (Fien berg, 1977). Results indicated that th simplest model that described the observe frequencies was the two-way interaction be tween instructional set and verdicts, $\chi^2(6) = 1.21$, $p > .97$. None of the more complicate models (i.e., those involving the multiple vs single judgments factor) contributed an explanatory power to this Instructional Set × Verdict model. Put another way, the pattern of verdicts was accounted for by the main effect for timing of instruction. Table 1 shows that the instructions-before condition pro duced 37% guilty verdicts, compared to 59% in the instructions-after and 63% in the no instructions conditions.

A scalar variable was defined by combining subjects' verdicts with their confidence rat ings (confidence itself was unaffected by the independent variables). Specifically, positive confidence values were assigned to guilty ver dicts and negative values to verdicts of not guilty. Scores could thus range from −8 (maximum confidence in not-guilty verdict

to 8 (maximum confidence in guilty verdict). A 2 × 3 analysis of variance on this measure revealed one marginally significant effect for timing of instruction, $F(2, 101) = 2.90$, $p < .06$. Duncan's multiple-range test further indicated that subjects in the instructions-before condition were less likely ($p < .05$) to convict the defendant than were noninstructed subjects (means of −.94 and 2.35, respectively). Instructions-after ($M = 1.79$) and noninstructed conditions did not so differ. An analysis of variance on the probability-of-commission estimates yielded results that closely paralleled those for the verdict–confidence measure—the only significant effect was for timing of the judge's instruction, $F(2, 101) = 2.92$, $p < .06$. Only subjects who received instructions before the evidence viewed the defendant as less likely to have committed the crime ($p < .05$) than did the noninstructed subjects (mean percentage estimates of 64% and 77.6%, respectively); those who were instructed after the reception of evidence ($M = 73.1\%$) did not lower their probability-of-commission estimates.

Contrary to predictions, no significant differences were obtained on evaluations of evidence strength, interpretations of reasonable doubt, or self-ratings of interest and involvement. Interestingly, a close look at the reasonable-doubt data indicates that the overall estimate of reasonable doubt ($M = 86.07$) was almost identical to that previously reported for college students (Simon & Mahan, 1971, obtained a general estimate of 87% and an estimate of 85% when the crime was auto theft). Subjects thus believed that there should be at least an 86% chance that the defendant committed the crime in order to vote for conviction.

Finally, subjects demonstrated a moderately high level of recall, averaging 12.15 correctly recalled items from a total of 16.[3] Further analysis indicated that a main effect was obtained for timing of instruction on the number of case-related facts recalled, $F(2, 101) = 3.26$, $p < .05$. Surprisingly, subjects in the instructions-after condition recalled fewer items ($M = 11.30$) than those in either the instructions-before ($M = 12.51$) or noninstructed ($M = 12.69$) conditions. The presence of the instruction between the evidence and response assessment apparently inhibited recall.

Table 2
Pattern of Mid-Trial Verdicts for the Three Instruction Groups at Each of the Six Decision Points

Instruction and verdict	Decision point					
	1	2	3	4	5	6
Before						
Guilty	8	8	8	7	5	8
Not guilty	10	10	10	11	13	10
After						
Guilty	16	16	17	16	13	15
Not guilty	3	3	2	3	6	4
None						
Guilty	15	14	15	14	14	12
Not guilty	2	3	2	3	3	5

Note. Decision points 1–6 immediately follow the direct examination and cross-examination of the prosecution's two witnesses and the defendant.

In sum, the mere timing of instructions had an impact on jurors' final judgments. Results for the verdict–confidence measure tended to support the major hypothesis that instructions on the requirements of proof would reduce subjects' tendencies to convict (i.e., relative to no instructions) only when delivered prior to the introduction of testimony. Although the timing variable had no significant effect on interpretations of reasonable doubt, preinstructed subjects actually viewed the defendant as less likely to have committed the crime than either the instructions-after or no-instructions subjects. Those who received instructions at the end of the trial did not respond differently on the verdict and probability-of-commission measures from those who were never instructed. In fact, they even recalled fewer of the case-related

[3] Only the major facts in the case were tested. Moreover, these facts were typically repeated throughout the trial proceedings (e.g., the highway on which Ron Oliver was stopped was first mentioned during the prosecutor's opening statement and was reiterated during the examination of both the arresting officer and the defendant and during the closing arguments). As a result, the facts tested could not be classified for further analysis as pro-prosecution or prodefense, nor could they be located at a single point in the trial.

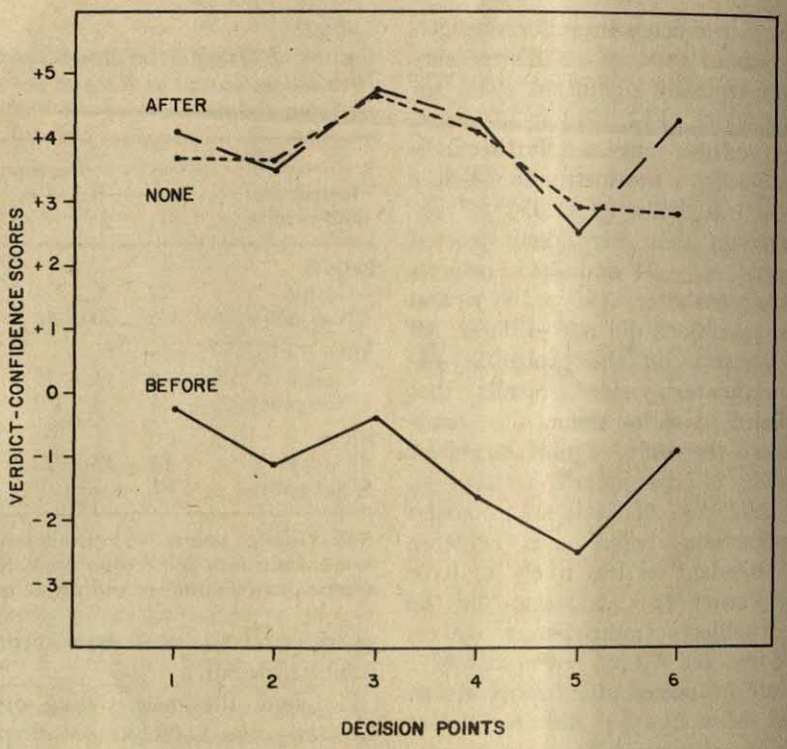

Figure 1. The pattern of verdict–confidence scores for the three groups at each of six decision points. (Higher scores indicate confidence in guilt.)

facts than all other subjects did. Finally, whether or not subjects made mid-trial judgments did not affect any of the above variables. The nonreactive nature of this multiple-judgment procedure was thus confirmed.

Process (Mid-Trial) Measures

Overall, 68% of the mid-trial responses were guilty verdicts. For the 54 subjects who made these judgments, the pattern of verdicts is presented in Table 2. As with the outcome data, these verdicts were analyzed with a likelihood ratio goodness-of-fit chi-square. Again, the simplest model that explained the observed frequencies was the two-way interaction between instructional set and verdicts, $\chi^2(30) = 6.50$, $p = 1.0$. Although a higher order model comprised of both Instruction × Verdict and Decision Point × Verdict interactions also fits the data, $\chi^2(20) = 3.13$, $p = 1.0$, it did not contribute significantly to the predictions made by the simpler model. Mid-trial verdicts were thus accounted for by th effect for instructional set. Table 2 shows th across all decision points the instruction before group yielded 41% guilty verdict compared to 82% in both the instruction after and no-instructions groups.

A verdict–confidence measure was agai created and was this time submitted to 3 (Instructions) × 6 (Decision Point) analy sis of variance. Figure 1 illustrates the stron main effect for the instruction factor, $F($ 51) = 10.15, $p < .001$, on these verdi scores. As before, this analysis clearly indi cated that subjects who were instructed to fore the evidence ($M = -1.14$) were con sistently less likely to convict the accused (p .001) than were either the instruction after or noninstructed subjects ($Ms = 3.0$ and 3.65, respectively). These latter group did not differ. An additional main effect f the decision point factor, $F(5, 255) = 4.$ $p < .001$, indicated, as expected, that verdi scores fluctuated widely as the trial pr

Table 3
Correlation Coefficients of Mid-Trial and Final Verdict–Confidence Scores in Each Group and Across All Groups

Group	Verdict–confidence score					
	1	2	3	4	5	6
Before	.14	.42	.57**	.46**	.42	.54*
After	.22	.22	.18	.15	−.03	−.15
None	.31	.30	.37	.42	.45	.86***
Overall	.28*	.41**	.47***	.44**	.36**	.52***

Note. Correlations are based on *n*s of 18, 19, and 17 ($N = 54$).
* $p < .05$. ** $p < .01$. *** $p < .001$.

gressed. As might be anticipated, the conviction rate was highest at the third point—right after the prosecutor examined his second witness ($p < .01$), and lowest at the fifth point—right after the direct examination of the defendant ($p < .01$). The interaction between instructional set and decision point did not approach significance ($F < .1$).

On the question of whether jurors' early impressions were predictive of their final predeliberation verdicts, Table 3 presents the correlations between subjects' mid-trial and final verdict–confidence scores. It can be seen that over all multiple-judgment groups the average correlation between mid-trial and posttrial verdict scores was .44 ($p < .01$). In fact, the average correlation between the verdict scores rendered at even the first decision point and those given at the end of the trial was .28 ($p < .05$). To some extent, then, subjects' decisions were substantially formed very early in the trial presentation.

Results for the repeated probability-of-commission measures followed a similar pattern (see Figure 2). A main effect for timing of instruction, $F(2, 5) = 6.58$, $p < .005$, re-

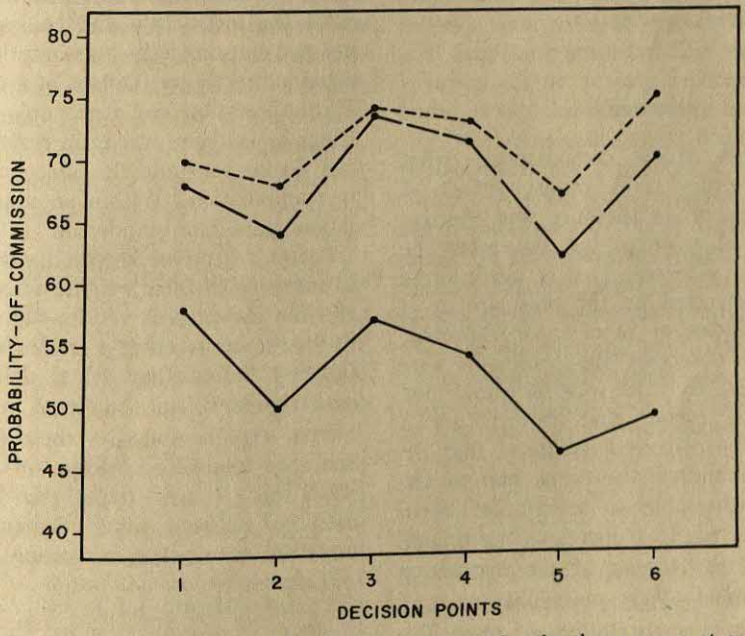

Figure 2. The pattern of probability-of-commission estimates for the three groups at each of six decision points.

vealed that during the trial, the instructions-before group ($M = 52.5\%$) viewed the defendant as less likely to have committed the crime ($p < .01$) than either the instructions-after or no-instructions groups (68.16% and 71.67%, respectively), who again did not differ from each other. Moreover, a main effect for the decision point factor, $F(5, 255) = 3.08$, $p < .01$, indicated that the perceived probability of commission was lowest at the fifth point—right after the defendant testified in his own behalf.

In sum, subjects' mid-trial judgments fluctuated in the predicted directions (i.e., guilty judgments after the prosecutor's examination and not-guilty judgments after the defense's examination). More important, these judgments were influenced largely by whether or not subjects had been instructed on the requirements of proof. That is, although instructional set and decision point did not interact (i.e., their curves were almost perfectly parallel, thereby indicating that pre-instructed subjects were neither less influenced by the prosecutor's testimony nor more influenced by the defendant's testimony), subjects who had been instructed before the evidence immediately and continually viewed the defendant as less likely to have committed the crime.

Discussion

The present study demonstrated what might be described as a primacy effect. A judge's instruction to the jury was effective when delivered prior to but not after the presentation of evidence. That is, mock jurors who were instructed on the presumption of innocence, burden of proof, and reasonable doubt before observing the testimony were ultimately less likely to vote for conviction. It was noted earlier that verdicts are a function of the perceived likelihood that the defendant committed the crime and of the standard or threshold to which that likelihood is compared. In the present experiment, variations in the timing of the instruction affected estimates of the probability of commission but not interpretations of reasonable doubt. Subjects who received the instructions before the evidence thus demonstrated a low rate of conviction because they actually viewed the defendant as less likely to have committed the crime.

Although the present experiment was not theoretically guided, it now appears that an information integration model of juror judgments (Kaplan & Kemmerick, 1974) might well describe the results. Briefly, each piece of evidentiary and nonevidentiary information possesses some scale value along a dimension of guilt–innocence and a weight that determines the importance of that information. A trial judgment is then formed on the basis of a weighted-average combination of stimulus components. In the context of the present study, subjects received two global categories of information: the trial presentation and judicial instruction. From the probability-of-commission responses of noninstructed subjects, the scale value of the trial information may be estimated at .78 (i.e., .78 is the marginal mean for noninstructed subjects). Although the scale value of the requirements of proof instruction was not assessed in the present study, it should—by legal ideal—have implied a scale value or initial probability of commission of 0 (Ostrom, Werner, & Saks, 1978). On the assumption that the scale values of the instruction and trial presentation remained constant (these assumptions are supported indirectly by the lack of a timing effect on interpretations of reasonable doubt and ratings of evidence strength, respectively), to what do we attribute the effects for the timing manipulation? Within an impression formation paradigm, Anderson (1965) found that later adjectives keep a fixed scale value but decrease in their weight. This mechanism describes the present results—the prodefendant instruction received a greater weight when delivered before than when delivered after the evidence.[4]

What *process* underlies these findings? At least two plausible mechanisms are worth evaluating. It was hypothesized that pre-instructed subjects would demand a greater burden of proof when evaluating the strength

[4] Note that although the present analysis treats judges' instructions as information that has a scale

of the prosecutor's case as it unfolds during the trial. This critical, evaluative "schema" was expected to manifest itself in different fluctuating patterns in the responses of the instructed (instructions-before) and noninstructed (instructions after and no instructions) mid-trial judgment groups. However, the absence of an Instruction × Decision Point interaction on verdicts and probability-of-commission ratings ruled out this hypothesis. In fact, the three instruction groups demonstrated remarkably similar mid-trial shifts in judgment (see Figure 1). Those who had been instructed were neither more influenced by the defense nor less influenced by the prosecutor than the others were. Instructed subjects thus did not reject or distort the prosecutor's evidence to fit an initial impression or presumption of innocence. And why should they? Luchins (1957) has demonstrated that by forewarning observers of the imminence of additional information, the proactive effects of early information on subsequent information are suppressed. Subjects in the present study and jurors in general *expect* to be confronted with inconsistent information. Early information in this setting (i.e., judicial instruction) is thus unlikely to produce the strong bias that would stimulate the processes of discounting or assimilation.

The process that did appear to operate was considerably less complex. Subjects who were instructed before the evidence were more likely than the others were to vote for acquittal and indicated a lower probability of commission *even from the first decision point*. Although they responded similarly to testimony that followed, their initial leanings resulted in fewer guilty verdicts at the conclusion of the trial. The impact of this initial reaction is reflected in the significant correlation between first and final verdict scores. Simply put, most preinstructed subjects "presumed innocent," whereas the others "presumed guilty."

The *practical* implications of the present study are straightforward. Mandatory code provisions do not forbid or discourage judges from using their discretion in instructing the jury before the trial. A number of states (e.g., Indiana, 1966), individual judges (e.g., Prettyman, 1960), and legal scholars (e.g., McBride, 1969) have thus adopted or advocated delivery of preliminary instructions prior to the presentation of evidence. In Missouri (1964), for example, the Supreme Court Committee on Jury Instructions recommended that "the jury be instructed before the trial begins. . . . The committee believes that it is better to draw the jury's attention to these matters before the trial rather than waiting until after the jurors may have reached a decision" (quoted in McBride, 1969, p. 62). This latter example is unfortunately an exception rather than the rule, which is that preliminary instructions are vastly underutilized (DeVitt & Blackmar, 1977). Viewed in this context, the present study provides firm support for proponents of procedural reform in the courtroom. The Anglo-American system of justice has traditionally favored the accused on the philosophy that acquitting a truly guilty person is better than convicting a truly innocent one (Ploscowe, 1935). Yet the present results suggest that the accused may not benefit from this protective instruction unless it is delivered to jurors *before* the trial. In this regard, perhaps the requirements of proof might well be included in the currently popular "juror handbooks" that are distributed to jurors as part of a pretrial orientation (National Institute of Law Enforcement and Criminal Justice, 1975) and might perhaps be presented at both the beginning and the end of the proceedings (Elwork et al., 1977).

From a methodological standpoint, the multiple-judgment procedure initially employed by Weld and Danzig (1940) merits increased consideration in future research. The present study confirmed that it does not bias jurors' ultimate verdicts or any other posttrial measures (also see Pyszczynski, Note

---

value and weight, Kaplan and his colleagues are quick to point out that strictly speaking, because instructions do not pertain to the specific defendant or crime, they do not relate to information scale value (S_i). Instead, instructions should affect an initial impression of the defendant that exists prior to jurors' receiving information about him or her (S_o), that is, the impression of defendants in general (see Kaplan & Miller, 1978).

1). Moreover, it appears to be valuable for examining jurors' reactions to the trial as it unfolds. Questions concerning the relative impact of different trial phases (e.g., opening statements and closing arguments, direct examination vs. cross-examination) and different kinds of evidence (e.g., tangible exhibits, expert or eyewitness testimony) may be fruitfully investigated through the mid-trial assessment of verdicts.

Finally, some of the limitations of the present results deserve mention. As with other nonevidentiary factors, the timing of an instruction cannot be expected to influence the outcome of a one-sided case (i.e., an extremely strong or weak case against the defendant). Rather, the effects should be considered limited to close, ambiguous cases. Note also that the present experiment assessed the verdicts of nondeliberating jurors. Whether or not deliberation provides enough of a corrective strategy to erase the timing effect upon juries remains open to question. Finally, the trial used in the present study was much shorter than the average criminal case. Whether or not the timing manipulation would affect jurors' responses in realistically longer trials remains to be seen.

Expectancy Shifts and the Expectancy Confidence Hypothesis

Richard W. Wollert
Portland State University

Explanations of differences in the size of expectancy changes following task outcomes were considered. The *control perception* hypothesis, the most frequently proposed explanation, is that small expectancy shifts occur when task outcomes are perceived to be externally (i.e., chance) controlled. An alternative explanation, the *expectancy confidence* hypothesis, is that small shifts occur when subjects are relatively confident of the accuracy of their expectations. Two experiments examined these positions. Experiment 1 partially replicated a study often cited as supporting the control perception hypothesis. Expectancy confidence was assessed, and as predicted by the expectancy confidence hypothesis, expectancy shifts were found to be related negatively to expectancy confidence. Skill perceptions and levels of expectancy confidence were manipulated in Experiment 2, and their impact was assessed by several expectancy shift measures. Expectancy confidence was found to influence expectancy shifts as predicted for four of five measures, whereas skill perceptions did not significantly affect expectancy shifts on any measure. Expectancy confidence thus exerts a substantial impact upon expectancy shifts. The relevance of the findings for a third explanation of expectancy shifts, the *causal stability* hypothesis, is discussed, as are the implications of the expectancy confidence hypothesis for theories of personality and depression.

For the last 25 years, expectancy for reinforcement has remained a fundamental concept of Rotter's social learning theory of personality (Rotter, 1954; Rotter, Chance, & Phares, 1972). A corollary of Rotter's belief that expectancies influence personality processes is that changes in these expectancies are important psychological phenomena. In Rotter's analysis, expectancy changes are considered to reflect learning about behavioral outcome relationships and to be precursors o behavior change.

Because of their significance for learnin and behavior change, many attempts hav been made to outline the conditions underl ing changes in expectancies for success. Tw general findings serve to put these efforts i broad perspective. First, subjects typicall raise their expectations after successfully per forming a task and lower them after unsuc cessful performance (cf. Rotter, Liverant, & Crowne, 1961). Second, large differences in expectancy changes exist between subject even where initial expectancy levels have bee equated and the pattern of task outcomes ha been controlled (cf. Miller & Seligman, 1973) Taken together, such findings indicate tha recent and direct task experience exerts a powerful influence on expectancy changes bu is not sufficient to account for all between subjects differences.

Rotter has proposed that several cognitive variables, termed "generalized expectancies

Some of the research reported in this article was part of a doctoral dissertation submitted to the Graduate School of Indiana University and was supported by a research grant from the Graduate School. Portions of this article were presented at the annual conventions of the Western Psychological Association, Seattle, 1977, and San Diego, 1979. The author is indebted to Alexander M. Buchwald, chairman of his dissertation committee, and to other committee members, Leon H. Levy, Richard D. Young, and Paul Gebhard. Many thanks also are extended to Bob Knight and Michele Smith for their assistance with the pilot studies, and to Stephen West for his helpful comments on the manuscript.

account for these individual differences. The most well known of these is internal versus external locus of control of reinforcement. According to Rotter (Rotter et al., 1972), small changes in verbalized expectancies occur where subjects perceive reinforcements to be externally rather than internally controlled. This view, which will hereafter be referred to as the *control perception* hypothesis, has been supported by several findings (Miller & Seligman, 1973; Phares, 1957; Rotter et al., 1961) that subjects faced with chance tasks (i.e., where task outcomes were perceived to be externally controlled) changed their expectancies of success less than subjects faced with skill tasks (i.e., where task outcomes were perceived to be internally controlled).

This hypothesis has had a significant impact on many areas of psychology. It has, as already noted, been used in social and personality psychology research to explain why subjects learn more about behavior-outcome relationships on some tasks than on others (Rotter et al., 1961). It has also been applied to the field of psychotherapy, where increases in a client's internal locus of control are often seen to precede both expectancy shifts and positive behavior changes (Rotter et al., 1972). Still a third application has come in the area of psychopathology. Seligman and his associates have found that depressives change their expectancies for success on skill tasks less than nondepressives (Klein & Seligman, 1976; Miller & Seligman, 1973). Relying on the control perception hypothesis, they have interpreted this finding to mean that depressives perceive reinforcement to be under greater external control than nondepressives do. This interpretation is consistent with Seligman's learned helplessness theory of depression (Seligman, 1975).

It should be recognized that these conclusions are justified only as long as the control perception viewpoint provides the most adequate explanation of expectancy shifts. This paper reviews and critiques some of the research supporting the control perception hypothesis and presents an alternative theory of expectancy shifts called the *expectancy confidence* hypothesis. The results of several studies supporting this alternative are then reported. Finally, the implications of the expectancy confidence hypothesis are discussed for theory and research on personality and abnormal psychology.

Review and Critique of the Control Perception Hypothesis

The two studies most frequently cited in support of the control perception hypothesis were conducted by Phares (1957) and Rotter, Liverant, and Crowne (1961). In the first study, Phares manipulated perceptions of control of reinforcement by giving subjects different pretask inductions. Phares discovered that smaller expectancy shifts were reported when a task was preceded by a chance induction rather than a skill induction.

In the second study, Rotter et al. assigned subjects to either a prediction or motor task. It was assumed that, "on the basis of previous cultural experiences" (Lefcourt, 1966, p. 208), subjects would perceive outcomes of the prediction task to be chance dependent. Outcomes were controlled so that success occurred on the first trial of each task. The prediction of Rotter et al. that chance task subjects would change their expectancies less than the other subjects was subsequently confirmed by several expectancy shift measures: (a) from the first to the second trial; (b) over all trials in which shifts in the appropriate direction occurred (i.e., upward or downward shifts in expectancies following success or failure, respectively, on the immediately preceding trial); (c) the final expectancy, recorded after the eighth trial. On the bases of these and earlier results, Rotter et al. concluded that the control perception hypothesis had been strongly supported.

The control perception interpretation of these two studies may be questioned on several grounds. A prime objection to Phares' approach is that neither initial expectancy differences nor expectations for improvement were assessed. However, the inductions placed such different emphases on task difficulty that they may have differentially affected initial expectations. Skill inductions, for example, pointed out that subjects performed at various levels, whereas chance inductions indicated that the task was "so difficult that it

did not differentiate between people . . ." (Phares, 1957, p. 340). Failure to assess initial expectancies and expectations for improvement is a serious weakness, given these inductions, since they conceivably created expectancy differences that later affected the size of expectancy changes.

Significant objections may also be raised to the methodology employed by Rotter et al. (1961). No manipulation check was conducted, for example, to determine if subjects perceived the tasks as skill or chance. It is consequently unclear whether the tasks were actually perceived as determined by skill or by chance. Equally important, the skill task differed greatly from the chance task. The possibility thus exists that task factors other than skill or chance perceptions may have led to the reported expectancy shift differences.

To these methodological drawbacks may be added the criticism that the control perception hypothesis has not received consistent empirical support. James and Rotter (1958) had subjects perform identical prediction tasks but manipulated perceptions of control by skill and chance inductions. They found that "the acquisition (i.e., raw expectancy) curves of the 100% (reinforcement) groups are fairly similar, as are the 50% groups" (p. 400). If raw expectancy curves are similar, there is no possibility that expectancy shifts may differ. This follows because differences in expectancy shifts may be defined as differences in the slopes of two expectancy curves at the same point. The findings of James and Rotter thus conflict with the findings of Phares (1957).

This lack of empirical support is apparent in correlational as well as experimental studies. Miller and Seligman (1973), found no relationship between expectancy shifts and personality measures that assess generalized perceptions of internal and external control of reinforcement. Consistent with this result, other authors have concluded that perception of control, when treated as a personality dimension, rarely has been found to be related to expectancy shifts (Weiner, Nierenberg, & Goldstein, 1976).

A final reservation applies not only to the research of Phares (1957) and Rotter et al. (1961) but to almost all studies of expectations for reinforcement. As defined by Rotter, expectancy for reinforcement is the "probability held by the individual that a particular reinforcement will occur as a function of a specific behavior on his part in a specific situation or situations" (Rotter et al., 1972, p. 12). In spite of this definition, however, subjects in expectations studies have consistently been asked to report how *sure* or how *certain* they were that they would succeed on a task. This question is not the same as asking subjects to report their *chances* of success. In fact, it may be argued that this method of assessment did not focus upon expectancies of success, but on how confident subjects were that an expectancy of success having the probability of 1 was accurate. Previous studies, therefore, may have confounded subjective expectancies of success with confidence in the accuracy of these expectations.

To summarize, in some cases adequate control has not been exercised over the effects of different tasks on expectancy shifts. Where tasks have been controlled, pretask inductions may have created initial differences in expectations for success and improvement. In addition, the results of different studies have conflicted. Finally, the assessment of subjective expectancies seems to have been confounded consistently with assessing confidence in the accuracy of these expectancies. Given these difficulties, it may be argued that the cognitive factors most importantly involved in expectancy shifts have not yet been clearly isolated.

The Expectancy Confidence Hypothesis

A possible alternative explanation of the findings of Phares (1957) and Rotter et al. (1961) stems from the expectancy confidence hypothesis. This hypothesis is based on the premise that individuals not only possess beliefs about their probabilities of success or reinforcement but also hold beliefs about the accuracy of these expectations. Expectancy confidence may be defined in terms of this certainty or, more formally, as the probability held by an individual that his or her expectancy is correct. For example, when such

jects hold that only expectations in a narrow range are plausibly accurate estimates of their chances of success, they possess high levels of expectancy confidence. Alternatively, when subjects will accept many expectations as plausible estimates, they have low levels of confidence.

If we contrast locus of control with expectancy confidence, a fundamental conceptual difference between approaches becomes apparent. While locus of control emphasizes specific beliefs, expectancy confidence emphasizes the relationships between cognitions in terms of certainty as defined by the range of plausible alternatives. Adopting Levy's (1970) terminology, locus of control may be considered to deal with the content of cognitions, whereas expectancy confidence deals more with the structure of cognitions.

The central proposition of the expectancy confidence hypothesis reflects this structural emphasis. That proposition is that the degree of change in expectancies that occurs over time or events is a function of expectancy confidence. When expectancy confidence is low, expectancies are likely to change; when expectancy confidence is high, expectancies are likely to remain stable. Applied to the findings of Phares (1957) and Rotter et al. (1961), the expectancy confidence hypothesis suggests that chance condition subjects may have been more confident of their expectancies than other subjects were. An analysis of some of the experimental procedures followed in these studies underscores the plausibility of this suggestion. For example, Rotter et al. (1961) informed chance condition subjects that their objective was to predict correctly whether slides marked with an *X* or an *O* would be projected upon a screen. In all likelihood, subjects had had some previous experience with gambling games or other situations similar to this task (e.g., predicting the toss of a coin). In the skill condition, the goal was to raise a steel ball resting on a movable platform above a certain height (Sky, 1950). Subjects in this condition probably had almost no prior experience with similar games or situations. Greater task experience presumably induced a relatively high level of confidence on the part of chance condition subjects that their initial expectations of success were correct. Since they were more confident of their expectations, subjects in the chance condition were less likely to change these expectations than were subjects in the skill condition.

In the Phares (1957) study, chance inductions stressed both task difficulty and lack of variation in task performance. It seems that this would lead chance condition subjects to expect to perform poorly and also to believe that their performance would not improve. In other words, chance subjects may have held more negative expectations than skill subjects held and may also have believed that these expectations were accurate estimates of their objective probability of success. With respect to this analysis, it should be pointed out that no mention of task difficulty or performance variation was included in the chance induction used by James and Rotter (1958). Levels of expectancy confidence may consequently have been somewhat similar for their skill and chance subjects. This could account for the lack of expectancy shift differences they found.

Data from several pilot studies conducted by the present author support the logic of this analysis. In one, the apparatus and descriptions for the tasks used by Rotter et al. (1961) were presented in a group setting to 49 undergraduates. Since a slide projector was unavailable, the prediction task was slightly modified so that sample letters were presented on 4″ × 6″ (10 × 15 cm) file cards, and subjects were told that their task was to guess correctly the letters on sets of file cards (rather than on slides). All subjects picked one of the tasks to complete this sentence: "I have more general experience with tasks similar to the [platform lifting or prediction] task." As predicted, a greater proportion of students (.76) reported more experience with the prediction task ($p < .001$).

In a second study, the color and line tasks and inductions used by Phares were presented to a group of 40 undergraduates. The color task was paired with the chance induction, and the line task with the skill induction. Subjects were asked to circle their best estimate of their chances of success on an 11-

point scale ranging from 0 to 100%. They also checked all the alternative estimates they considered plausible. This made it possible to determine their highest and lowest plausible chances of success as well as their best estimate. As predicted, paired t tests showed that all three expectancy variables were less for the chance induction task than for the skill induction task (all p's $\leq .001$). When we paired the color task with the skill induction and the line task with the chance induction in a later administration to 50 undergraduates, this finding was replicated.

In the following two experiments, the expectancy confidence hypothesis has been examined in a more precise fashion and under more carefully controlled conditions.

Experiment 1

In an effort to determine whether the expectancy confidence hypothesis provides a plausible explanation of the findings of Rotter et al. (1961), a partial replication of this study was conducted. The following predictions, based upon the expectancy confidence model, were tested:

1. Subjects presented with the chance task would report that they were more confident of their initial expectations than would subjects assigned to the skill condition. This follows from the expectancy confidence position that subjects who report small expectancy shifts should also be confident that their initial expectations are correct.

2. Expectancy shifts from Trial 1 to Trial 2 would be correlated negatively with initial measures of expectancy confidence within conditions. In other words, the negative relationship between expectancy confidence and expectancy shifts was expected to hold within conditions as well as between conditions.

3. Expectancy shifts from Trial n to Trial $n + 1$ would be correlated negatively with expectancy confidence on Trial n for the subjects within each condition; that is, the relationship between expectancy confidence and expectancy shifts was expected to hold within subjects as well as within conditions.

4. Trend analysis of expectancy confidence over all trials would show an increase in confidence within the skill condition. This hypothesis was based on the presumption that subjects are usually unfamiliar with the task used in this condition and that expectancy confidence will increase as experience increases. A similar hypothesis was not stated for subjects in the chance condition, as it was assumed that they had had more prior experience with the chance task.

Method

Subjects

Subjects were 51 female college students enrolled in introductory psychology courses. Female subjects were used because Rotter et al. used females and because this increased the homogeneity of the subject samples. Eleven of these subjects were eliminated from the data analysis: 4 because of apparatus failure, 5 because they suspected the skill task was unfair, 1 because she suspected the chance task was unfair, and 1 because she did not perform the skill task as directed.

Apparatus

Chance task. Slides were projected onto a screen 8 feet (2.46 m) in front of the subject. Subjects were informed that some of these slides were imprinted with an *X* and that others were imprinted with an *O*. Before a slide was projected, subjects were to guess whether an *X* or an *O* would appear. To be successful on a "trial," a subject had to predict correctly four out of five presentations.

Skill task. The skill task, hereafter referred to as the "Sky" task, involved an apparatus similar to that originally developed by Sky (1950) and later used by Rotter et al. (1961). Each subject was requested to raise a 4-inch (10 cm) square platform upon which a ½-inch (13 mm) steel ball bearing had been placed. The platform was to be raised by gently pulling on a string connected to the platform and threaded through a pulley at the top of the Sky apparatus. To be successful, it was necessary to lift the platform 9 cm without the ball rolling over one of the edges. The ball, positioned by the experimenter, was held in place by an electromagnet implanted on the underside of the platform. Current to this device could be interrupted by depression of a concealed, silent solenoid switch. Since the platform of the apparatus sloped forward very slightly, the ball would roll off the platform when such an interruption occurred. Outcomes could therefore be surreptitiously controlled by the experimenter.

Assessment. To report expectancies of success, subjects answered the following question using an 11-point scale running from 0 to 100% (i.e., 0%, 10%, 20%, etc.): "What are the chances that you will succeed on this task? In other words, if you did this

task over and over, what percent of the time would you be successful?"

To report expectancy confidence, subjects answered the following question on a 5-point scale ranging from "very good idea" to "almost no idea": "How good an idea do you really have of your actual chances of success?"

Subjects reported perceptions of control of reinforcement by responding to the following question on an 11-point scale ranging from 0 (success depends on chance) to 10 (success depends on skill): "How important is skill or chance in producing success on this task?"

Procedure

Twenty subjects were randomly assigned to each condition. Data were collected for each subject individually.

Subjects were seated and a prepared script[1] was read by the experimenter. The first section of the script described whichever task the subject was to receive. Subjects were then given printed forms of the questions assessing expectancies and confidence and were provided with examples of how they might answer these if they were to report high or low ratings of expectancies of success or expectancy confidence. After the experimenter answered any remaining questions, subjects recorded their answers to the questions. The question assessing perceptions of control of reinforcement was then explained, and a rating was obtained from the subject.

After completing the third question, subjects were given eight trials on either the chance or skill task. Success was controlled at a rate of 50%,[2] and all subjects were presented with an identical pattern of outcomes (success, failure, failure, success, success, failure, failure, success). In the chance task, the experimenter exerted control by either advancing or reversing the slide tray in response to the subject's predictions. In the skill task, outcomes were controlled by depression of the silent solenoid switch. The outcome of every trial (i.e., success or failure) was announced to subjects immediately after it was completed. Each subject then reported her expectancy of success and expectancy confidence for the next trial. After the last trial, a final rating of perception of control of reinforcement was obtained in addition to the other ratings.

Following the data collection period, subjects were asked what they thought was the hypothesis of the experiment, whether they fully understood the questions, and whether they believed that the task was unfair. No subjects correctly guessed any of the experimental hypotheses or indicated that they did not understand the questions. Data for subjects who believed the task was unfair (e.g., some thought that the platform was not level or believed that the experimenter had some means of controlling the outcomes) were eliminated from the final analysis.

Results

Before data analysis, indices of expectations of success and expectancy confidence were produced, as follows:

Expectations of success for Trial n = raw expectations score × 10;
expectancy confidence for Trial n = raw expectancy confidence score/4 × 10.

These transformations simply allow all responses to be presented as if they had come from 11-point scales, where 0 represented minimal ratings of skill perception, expectancy confidence, or expectations of success.

Preliminary data analysis[3] indicated that the three dependent measures were not intercorrelated significantly before Trial 1 within either condition (product–moment r values between .00 and .23). Consequently, pretask expectancies of success, levels of expectancy confidence, and perceptions of skill requirements are assumed to represent relatively separate dimensions.

Further data analysis, summarized in Table 1, pointed to the conclusion that the results of Rotter et al. (1961) were replicated in the current study. Using t tests for independent means, we found that subjects assigned to the two groups did not differ in their initial expectations of success, $t(38) = 1.77$, $p > .05$. However, skill condition subjects displayed significantly greater expectancy shifts than did chance task subjects from Trial 1 to Trial 2, $t(38) = 4.66$, $p < .001$. In addition, subjects did perceive the Sky task as requiring greater skill than the prediction task, both before the first trial, $t(38) = 5.58$, $p < .001$, and following the last trial, $t(38) = 4.25$, $p < .001$.

More important for the expectancy confidence position, Hypothesis 1 was confirmed. That is, subjects in the chance condition were

---

[1] The scripts used in both experiments have not been included because of space limitations. They are available from the author.

[2] When expectancy shifts under four different reinforcement conditions (25, 50, 75, and 100%) were observed, Rotter et al. (1961) discovered that similar shift discrepancies took place under all conditions. Therefore, to focus upon only a single condition of success was sufficient for the present study.

[3] All tests of significance were two-tailed.

Table 1
Means and Standard Deviations for Skill and Chance Condition Subjects in Experiment 1

Measure	Chance		Skill		
	M	*SD*	*M*	*SD*	*t*
Expectations of success	3.45	1.28	4.30	1.72	1.77
Expectancy shifts, Trials 1 to 2	.75	.97	2.55	1.43	4.66**
Skill perceptions, pretask	1.90	1.33	4.85	1.95	5.58**
Skill perceptions, posttask	3.30	2.20	5.90	1.61	4.25**
Expectancy confidence	3.88	2.50	1.62	2.03	3.13*

Note. All *t* tests for independent means were two-tailed. $n = 20$ in each group.
* $p < .01$. ** $p < .001$.

found to be significantly more confident of their expectancies than were subjects in the skill condition, $t(38) = 3.13$, $p < .01$. Hypothesis 2 was partially confirmed, since a significant negative product-moment correlation was found between expectancy confidence on Trial 1 and expectancy shifts from Trial 1 to Trial 2 within the skill condition, $r(18) = -.50$, $p = .02$, although not within the chance condition, $r(18) = .16$, $p > .05$. Subsequent analysis revealed that the variance of initial shifts for the chance group was significantly less than that for the skill group, $F(19, 19) = 2.68$, $p < .05$, which may account for the low and nonsignificant correlation found for the chance group. No significant relationships between initial skill perceptions and initial expectancy shifts were found within either the skill condition, $r(18) = -.21$, $p > .05$, or the chance condition, $r(18) = .35$, $p > .05$.

Table 2
Means and Standard Deviations for Chance and Skill Condition Subjects in Experiment 1 for all Experimental Trials

Trial	Outcome	Expectancy confidence			
		Chance		Skill	
		M	*SD*	*M*	*SD*
1**	Success	3.88	2.50	1.62	2.03
2	Failure	4.50	2.08	5.12	1.51
3	Failure	5.00	2.29	5.00	1.40
4	Success	4.25	2.82	5.00	1.81
5	Success	5.00	3.03	5.75	1.43
6*	Failure	5.38	2.84	7.00	1.54
7	Failure	5.25	3.13	6.62	1.86
8*	Success	4.50	3.10	6.25	2.07
9*	—	4.88	3.09	6.88	1.79

Note. All *t* tests for independent means were two-tailed. $n = 20$ in each group.
* $p < .05$. ** $p < .01$.

To test Hypothesis 3, product–moment correlations between expectancy confidence on Trial n and expectancy shifts from Trial n to Trial $n + 1$ were calculated for each subject over all eight trials. Correlations were transformed according to Fisher's r-to-z transformation, and the z values were averaged within each condition (McNemar, 1962). By testing for the significance of each z_{av}, the significance levels of the corresponding r_{av} values were determined. Hypothesis 3 was partially confirmed, since a significant negative average correlation was found within skill condition subjects, $r_{av} = -.49$, $p = .007$. A similar relationship was not found for chance condition subjects, $r_{av} = .16$, $p > .05$. Three subjects in the chance condition did not display any variance in expectancy shifts. Since the correlation is undefined in such cases, the data from these subjects did not contribute to the average correlations for the chance condition.

A test for linear trend revealed that expectancy confidence increased over the course of eight trials for subjects assigned to the skill condition, $F(1, 171) = 79.52$, $p < .001$. No such changes were noted for chance condition subjects, $F(1, 171) = 1.38$, $p > .05$. The fourth hypothesis, therefore, was also confirmed. Mean levels of expectancy confidence for each trial are shown in Table 2.

In order to analyze expectancy shifts most fully, it would be important to consider the fluctuations in expectancy shifts that occurred over the course of the experiment. An analysis of variance of a two-factor mixed design with

repeated measures on one factor revealed significant main effects for conditions, $F(1, 38) = 13.90$, $p < .001$, and trials, $F(7, 266) = 13.5$, $p < .001$, and a significant Conditions × Trials interaction, $F(7, 266) = 6.2$, $p < .001$. Inspection of the mean trial by trial expectancy shifts revealed that greater expectancy shifts occurred for skill task subjects than for chance task subjects over the first three or four trials and from Trial 1 to Trial 2 in particular. Differences in expectancy shifts decreased after the first few trials, so that they were virtually of the same magnitude for both groups by the end of eight trials.

In sum, the results of Experiment 1 confirmed, or partially confirmed, each hypothesis of the study.

Discussion

An analysis of expectancy shift research suggested that high expectancy confidence leads to small expectancy changes. This analysis also suggested that in an important expectancy shift study (Rotter et al., 1961), chance task subjects were more confident than skill task subjects that their initial expectancies were correct.

The first experiment evaluated these contentions. In accordance with the expectancy confidence hypothesis, subjects performing the prediction task in Experiment 1 were found to possess higher levels of expectancy confidence than subjects performing the platform task. Product-moment correlations also indicated that differences in expectancy confidence were related to expectancy shifts for subjects in the Sky task. Although similar differences were not found for prediction task subjects, subsequent analysis revealed that the variance of initial expectancy shifts was significantly less for subjects in this condition. McNemar (1962) has pointed out that the magnitude of a correlation coefficient is lessened when the range of either variable is curtailed. Therefore, although the relationship between expectancy confidence and expectancy shifts under chance conditions warrants examination in future studies, this explanation plausibly accounts for the correlational differences between skill and chance conditions in Experiment 1.

The first experiment also determined if subjects performing the Sky and prediction tasks perceived outcomes to be differentially dependent upon skill or chance factors as asserted by Rotter et al. (1961). Subjects did perceive the Sky task as requiring more skill than the prediction task. Skill perceptions were not, however, correlated with expectancy changes. In addition, the convergence of expectancy shifts reflected by the significant Conditions × Trials interaction is at odds with the control perception hypothesis. Since subjects rated the Sky task as requiring more skill than the prediction task, both before and after completing the tasks, the control perception hypothesis would seem to suggest that some differences in the size of expectancy shifts should have been observed throughout the experiment.

Experiment 2

Experiment 2 was an attempt to make comparative tests of predictions about expectancy shifts based on the expectancy confidence and control perception hypotheses. All subjects performed on the skill task used in Experiment 1. Expectations of success were recorded over several trials, thereby allowing for the calculation of expectancy shift measures similar to those frequently used by other researchers (cf. Klein & Seligman, 1976; Miller & Seligman, 1973; Rotter et al., 1961). Skill perceptions were manipulated by pretask inductions so that one group of subjects perceived outcomes to be skill dependent (high skill perception), whereas another group perceived outcomes to be chance controlled (low skill perception). Levels of expectancy confidence were also manipulated by pretask inductions so that one group of subjects was relatively certain that their expectancies of success were correct (high expectancy confidence), whereas another group was less certain of this (low expectancy confidence). These locus of control and confidence manipulations were combined factorially. The following hypotheses were tested:

1. Smaller expectancy shifts will be reported by subjects assigned to the low skill conditions than by those in the high skill conditions (the control perception prediction).

2. Smaller expectancy shifts will be reported by subjects assigned to the high expectancy confidence conditions than by those in the low expectancy confidence conditions (the expectancy confidence prediction).

Method

Subjects

Subjects were 97 female college students enrolled in introductory psychology courses. Seventeen subjects were eliminated from the data analysis: 1 because of apparatus failure, 2 because they did not operate the apparatus according to instructions, 7 because they suspected the task was not fair, and 5 because they reported that they either did not answer the questions properly (e.g., estimated expectancies on a trial by trial rather than on a long-term basis) or did not understand the objective of the task.

Instructions

All of the pretask instructions given to subjects performing on the skill task in Experiment 1 were presented to subjects participating in Experiment 2. In addition, instructions designed to induce particular perceptions of control of reinforcement and levels of expectancy confidence were delivered. These inductions had been found in pilot studies to be sufficiently powerful to create significant differences between groups with respect to skill perceptions and levels of expectancy confidence. The high skill subjects were informed that how they performed was determined by many factors under their control. The low skill subjects were told that how they performed was determined by many factors outside their control. The high confidence subjects were told that, of the college students who had performed the Sky task many times, 50% were successful more than half the time, and the other 50% were successful less than half the time. The low confidence subjects were told that 25% of their peers were successful on the task almost all the time, 25% were successful over half the time, 25% were successful less than half the time, and 25% were almost never successful. To clarify this information, these subjects were also presented with a figure indicating the rectangular distribution of performance scores. These confidence inductions were used on the reasoning that subjects given a performance distribution broken down into several categories would be less sure where their average performance scores might fall than other subjects given only two categories. In order to deliver the appropriate inductions in as uniform a manner as possible, one of four videotapes was presented to each subject.

The questions and scales used in Experiment 1 to assess perceptions of control of reinforcement, expectancy confidence, and expectations of success were also used in Experiment 2.

Procedures

Twenty subjects were assigned randomly to each of the four induction conditions. Data were collected for each subject individually. Since the data collection period spanned two quarters, a randomized block design (Winer, 1971) was adopted to control for fluctuations in subject characteristics.

After being seated at a table upon which the Sky apparatus had been placed, each subject was presented with videotaped instructions. After the videotaped instructions were presented, subjects performed the Sky task. The object of each trial was the same as that described in Experiment 1. Each subject participated in eight trials, with the pattern of outcomes being surreptitiously controlled by the experimenter, as in Experiment 1. Expectancies of success and expectancy confidence were reported before each trial and after the final trial. Skill perceptions were reported before the first trial and after the last trial.

Subjects were asked the debriefing questions used in Experiment 1. No subjects correctly guessed any of the hypotheses of the experiment, although several indicated that they believed the outcomes were controlled. Data for these latter subjects were eliminated from the final analysis.

Results

The analysis of variance applied to the data was a randomized block design with replications as an additional factor (Winer, 1971). Therefore, wherever analyses of variance were undertaken in Experiment 2, the following three factors were included: skill perception (two levels), expectancy confidence (two levels), and replications (four levels). Before data analysis, raw scores were transformed as in Experiment 1.

To make meaningful comparisons between groups, it was necessary first to determine whether the instructions were successful in producing the intended differences and also whether there were differences in initial expectancies that might account for later differences. When skill perceptions were analyzed, high skill subjects indicated that a higher level of skill was required for successful task performance than that indicated by low skill subjects, $F(1, 64) = 8.20$, $p = .006$. On measures of expectancy confidence, high confidence subjects were more confident than low confidence subjects that their initial expectancies were correct, $F(1, 64) = 11.36$, $p = .002$. All other main effects and interactions in these two analyses had F values less than 1.0.

Table 3
Means and Standard Deviations of Dependent Measures for Experiment 2

Measure	Experimental condition			
	Low skill–low confidence	Low skill–high confidence	High skill–low confidence	High skill–high confidence
Change, Trials 1 to 2				
M	2.20	1.45	2.85	1.90
SD	1.24	1.15	1.53	1.45
Total change				
M	5.70	3.70	6.70	4.50
SD	3.10	2.89	3.08	2.98
Total increase				
M	3.55	2.30	4.05	2.80
SD	1.96	1.75	2.21	1.99
Total decrease				
M	2.15	1.40	2.65	1.70
SD	1.39	1.31	1.63	1.26
Final expectancy				
M	5.80	5.45	5.15	5.60
SD	1.28	1.28	1.09	1.88

Note. $n = 20$ for all conditions.

Initial expectations of success were not influenced significantly by either the skill, $F(1, 64) = .42$, $p > .05$, or confidence, $F(1, 64) = 1.18$, $p > .05$, inductions, and a significant interaction was not found between inductions, $F(1, 64) = .13$, $p > .05$. Taken together, the preliminary analyses suggest that the expectancy shifts observed in Experiment 2 may be attributed to the manipulations rather than to some uncontrolled factor.

Measures employed to evaluate expectancy shifts included the following: (a) change in expectancies between Trials 1 and 2; (b) total increases in expectancies, defined as the absolute sum of the changes that occurred immediately following successful outcomes; (c) total decrease in expectancies, defined as the absolute sum of the changes that immediately followed failure experiences; (d) total amount of expectancy change, defined as the sum of total increases and decreases in expectancies; and (e) the final expectancy.

Table 3 contains the means and standard deviations of the dependent measures. Significant main effects were found for the confidence induction in the direction predicted by the expectancy confidence hypothesis for changes in expectancies from Trial 1 to Trial 2, $F(1, 64) = 8.91$, $p = .004$; total amount of expectancy change, $F(1, 64) = 8.95$, $p = .004$; total increase in expectancies, $F(1, 64) = 7.36$, $p = .008$; and total decrease in expectancies, $F(1, 64) = 7.05$, $p = .01$. The only measure not reflecting such differences was the final expectancy reported by subjects, $F(1, 64) = .02$, $p > .05$. A main effect for the skill induction approached the .05 level for changes in expectancies from Trial 1 to Trial 2, $F(1, 64) = 3.33$, $p = .07$. However, no significant main effects for the skill induction were found for any of the other dependent measures ($p > .20$ in all cases). In addition, no significant interactions were found ($p > .20$ in all cases).

Discussion

In Experiment 2, high and low levels of expectancy confidence were factorially combined with high and low skill perceptions. Comparative predictions based on the expectancy confidence and control perception hypotheses were tested. The prediction based upon the expectancy confidence hypothesis was supported by the finding that subjects with high levels of confidence changed their expectancies

less than subjects with low levels. Although high skill subjects reported that the Sky task required more skill than the low skill subjects said it did, skill perception differences did not significantly affect expectancy shifts. The prediction based upon the control perception hypothesis was therefore not supported.

General Discussion

Considering the contributions of each experiment separately, Experiment 1 pointed up naturally occurring relationships between variations in expectancy confidence and variations in expectancy shifts. Experiment 2 showed similar effects for manipulated levels of expectancy confidence. Taken together, the results provide strong support for the expectancy confidence hypothesis but not for the control perception hypothesis.

Generality of Applicability

The clear predominance of support given the expectancy confidence hypothesis raises the question whether all expectancy shift differences previously explained by the control perception hypothesis could now be accounted for by the expectancy confidence hypothesis. For example, could the findings of Rotter et al. (1961) be considered, on the basis of the results of Experiment 2, to be an artifact produced by dissimilar tasks? This probably is too strong a statement in view of the fact that skill perception differences were larger in Experiment 1, the replication of Rotter et al., than in Experiment 2. This observation suggests that the size of expectancy shifts could be affected differentially where large skill perception differences exist.

Another consideration that argues against premature closure on this issue is that a main effect for the skill induction in Experiment 2 approached the .05 level of significance for one expectancy shift measure. Several explanations of this finding are plausible. One straightforward account is that it may be understood in terms of random fluctuation. This view is supported by the fact that the use of five expectancy shift measures greatly increased the chances that one of the several measures would have a low p value. Another obvious possible explanation is that, under certain circumstances, perceptions of control may influence expectancy shifts independently of expectancy confidence. Confirmation of this possibility would limit the generality of the expectancy confidence hypothesis. This would not, however, negate the conclusion that the concept of expectancy confidence has a useful "range of convenience" (Kelly, 1955) for the comprehension and prediction of some behaviors.

In evaluating the generality of the expectancy confidence hypothesis, some attention should be given to other expectancy shift theories. Weiner's attributional theory is particularly relevant in this regard, since it has been explicitly offered to account for the results obtained by Rotter and his colleagues (Weiner, Frieze, Kukla, Reed, Rest, & Rosenbaum, 1971; Weiner, Heckhausen, Meyer, & Cook, 1972; Weiner, Nierenberg, & Goldstein, 1976). Weiner (Weiner et al. 1976) reviewed several empirical studies of the relationship between expectancy shifts and causal attributions that were stable and internal (skill), stable and external (task difficulty), unstable and internal (effort), and unstable and external (luck). He concluded that the greatest shifts occurred for subjects who attributed their outcomes to stable factors rather than to internal factors. Causal stability, as opposed to control perception, is thus considered by Weiner to be the major dimension underlying expectancy shifts.

While powerful tests of the expectancy confidence and causal stability hypotheses must await future research efforts, it is possible to make some comparative statements about these theories on the basis of the present findings. Weiner has argued that the skill and chance tasks used in Experiment 1 lead subjects to make stable and unstable attributions, respectively (cf. Weiner et al., 1972). He would presumably advance a similar interpretation of the effects of the skill and chance inductions used in Experiment 2. Such assertions would suggest many of the same hypotheses as those based on the control perception hypothesis:

1. Skill perceptions in Experiment 1 should

be positively correlated with the size of expectancy shifts.

2. Differences in expectancy shifts should be observed for skill and chance subjects in Experiment 1 on later as well as earlier trials.

3. A significant main effect for skill perceptions should be present in Experiment 2.

Since these hypotheses were not confirmed, whereas those derived from the expectancy confidence hypothesis were confirmed, the results of Experiments 1 and 2 support the expectancy confidence hypothesis but not the causal stability hypothesis.

A final theoretical dimension that should be related to the generality of the expectancy confidence hypothesis is that of commitment. Mischel (1958) and Watt (1965) have asserted that verbalization and discussion of initial expectancies increase the level of commitment to the specific values of these expectancies. Expectancy changes may therefore be small where commitment is high. Applying this formulation to the present research, it could be argued that reporting high levels of confidence induced high levels of expectancy commitment and that this led to small expectancy changes.

Although this explanation could account for the results of Experiment 2 and the correlational findings of Experiment 1, it should be pointed out that the relationship between commitment and expressions of confidence was not empirically determined in the present studies. Furthermore, by itself, a commitment hypothesis does not provide a clear explanation of the shift differences that have been found when confidence was not assessed and when commitment was presumably equalized as a result (cf. Miller & Seligman, 1973; Phares, 1957; Rotter, Liverant, & Crowne, 1961).

It is clear from this discussion that many variables may be involved in the production of expectancy shifts. It is also apparent that some post hoc alternative explanations may be formulated to account for the present results. In view of these circumstances, an advisible future research course would include developing several methods of manipulating important variables, devising unobtrusive measures for assessing these manipulations, and then completing additional comparative studies.

Implications

Methodological. Applications of the expectancy confidence hypothesis may be made to several areas. Perhaps the most straightforward of these falls on a methodological level. The nonsignificant correlations between initial expectancies and expectancy confidence in both experiments and the lack of initial expectancy differences between confidence conditions in Experiment 2 indicate that expectancies were independent of expectancy confidence. Unfortunately, the measurement of expectancies has consistently been confounded with expectancy confidence in previous research. This makes it difficult to interpret clearly many previously reported findings. Furthermore, from the standpoint of future research, it would seem extremely important to assess expectancy confidence separately whenever expectancies are assessed.

Theoretical. The expectancy confidence hypothesis also holds implications for personality and psychotherapy theories using expectancy constructs (e.g., Bandura, 1977; Rotter, 1954), in that it provides a new explanation of changes in expectancies and behavior. Rotter, for example, has proposed that behavior is a function of expectancies for reinforcement and reinforcement value (Rotter, 1954; Rotter et al., 1972). Where reinforcement value remains constant, changes in expectancies for reinforcement have typically been considered necessary preconditions for behavior change. A formulation of behavior change that takes into account the importance of expectancy confidence suggests that low levels of expectancy confidence are antecedents of changes in expectancies and behavior.

Another application of the expectancy confidence hypothesis lies in the reinterpretations it provides of previous research based on the control perception hypothesis. As pointed out in an earlier section, it not only accounts for the findings of Phares (1957) and Rotter et al. (1961) but reconciles these findings with those of James and Rotter (1958). It also holds implications for research on the learned-

helplessness model of depression. Seligman's (1975) interpretation of the low expectancy shifts of depressed undergraduates as evidence for this model rests not only on the explicit assumption that expectancy shifts are greater for skill tasks than chance tasks but also on the implicit assumption that there are no other sources of differences in the size of expectancy shifts. The present results contradict these assumptions by indicating that expectancy confidence is an important source of differences that has not previously been taken into consideration. The present results thus call into question evidence that has been thought of as providing strong support for the learned-helplessness model.

An alternative explanation of the association between depression and small expectancy shifts is that depressives shift their expectations less than nondepressives because they are more confident of their expectancies. At first, this might seem illogical. However, it appears more reasonable when the nature of the certainty associated with depression is considered. The findings of Friedman (1964) and Loeb, Beck, and Diggory (1971) indicate that one of the hallmarks of clinical depression is extreme negativity regarding self-evaluation and expectations of successful performance. Beck (1967) has also observed that depressives cling to such beliefs with remarkable tenacity. Negative expectations of success and negative evaluations of performance have also been reported for populations of depressed undergraduates (Wollert & Buchwald, 1979). On the bases of these reports and the results of the present investigation, it is proposed that depressives shift their expectations less than nondepressives because they are relatively certain that they will neither succeed nor improve when confronted with a skill task.

The expectancy confidence hypothesis provides another explanation of expectancy shift differences and points to several important reinterpretations of previous results. It also holds implications for theories of personality, behavior change, and depression. This hypothesis emphasizes the structure of cognitions and seemingly provides additional breadth to personality theories based on expectancy constructs. To realize this potential, however, it will be necessary to integrate the construct of expectancy confidence with existing theories. Consideration of those factors possibly affecting expectancy confidence would also be required. Such factors include experience, task perceptions, the degree of internal consistency within an expectancy network, the number of plausible alternative expectancies, the availability of meaningful information, and the operation of interpersonal influence factors. In view of the numerous applications of the expectancy confidence hypothesis, further research along these lines would certainly appear warranted.

Components of Aggression in Chickens and Conceptualizations of Aggression in General

D. W. Rajecki, David R. Nerenz, Terry G. Freedenberg, and Patricia J. McCarthy
University of Wisconsin—Madison

A refined analysis of the peck order in chickens was offered as a test of the notion that for this species, different responses such as leaping and various types of pecking need not be interchangeable indexes of aggression. Indeed, tests showed that particular response types of the birds were differentially mediated by organismic or environmental factors. In large cages pecking at the body was most frequent by birds that had a home-cage advantage. Contrarily, rates of aggressive leaping were independent of this environmental influence, with males having an advantage over females. Males showed more head pecking than females, but the profile for this sex difference did not resemble the profile for leaping. Correlational analyses revealed that whereas head pecking between testmates was not matched in frequency, leaping was positively related. Finally, the behavior of birds tested in small cages differed from that of the large-cage subjects. Although there was more head pecking in the small cages, males did not have an edge, and leaping was infrequent. Such results indicate that these responses cannot be viewed as interchangeable indicators of aggression in fowl.

Our thesis is that certain indexes of presumably aggressive behavior cannot be used interchangeably in an uncritical manner. Where they exist, separate influences on different measures will require identification. Indeed, there is controversy over procedures and standards for classifying particular responses as aggressive in both the human (cf. Baron, 1977; Tedeschi, Smith, & Brown, 1974) and nonhuman (cf. Deag, 1977; Rowell, 1974; Syme, 1974) research domains. In terms of the latter literature, evidence is beginning to accumulate that in analyzing the social psychology of animals certain "components," "forms," or "types" of aggression (labels used by different writers) should not be used interchangeably.

To take the literature on rodents as an example, in intact rats there was no relationship between success in intraspecies fighting (in dominance encounters) and mouse killing (Baenninger & Baenninger, 1970), and although spontaneous dominance orders and limited access (competitive) dominance orders were reliable within themselves, they showed very low interorder correlation (Baenninger, 1970). Further, rats that would not normally engage in fighting (females and males familiar with one another) could be induced to fight in competition for food (Zook & Adams, 1975). Sensory alterations and other surgical preparations have also revealed differences in components of rat aggression. Whereas blinded rats fought at control levels in a shock situation, anosmic and devibrissaed pairs fought less, and olfactory bulbectomized animals showed an increase in mouse killing (cf. Bugbee & Eichelman, 1972; Ghiselli & Thor, 1975; Thor, 1976). Moreover, it has been demonstrated that shock-induced aggression

This research was supported by Grant 190245 from the Graduate School Research Committee of the University of Wisconsin. The authors are indebted to Marlowe Embree, Kurt Steuck, Therese Durkin, and Carol Sawyer for assistance in the research. In particular, the authors thank Mr. and Mrs. George Fujioka for determining the sex of day-old chicks.

is separable from territorial aggression in rats in terms of the differential influence of hypothalamic lesions on these two response types (Adams, 1971) and the differing behavioral profiles of intact animals across the two situations (Blanchard, Blanchard, & Takahashi, 1978).

Studies with mice parallel the rat literature (Fredericson, 1952; Rowe & Edwards, 1971), and a set of researches indicates that the components or patterns of aggressive displays in certain fishes are not uniformly influenced by experiential and environmental factors (Clayton & Hinde, 1968; Davis, 1975; Shapiro & Schuckman, 1971). Further, success in peck exchanges between young chicks does not correlate with their success in limited access tests (Rajecki, Nerenz, Barnes, Ivins, & Rein, 1977). Taken together, this growing body of evidence suggests that in the study of any species it may be necessary to forego the assumption that there is some unitary factor in all modes of aggression. This consideration brought us to an assessment of components of aggression in young domestic chickens.

In fact, a detailed analysis of aggression in chickens is quite warranted. Although the term *peck order* is widely used by both scientist and layman, there is surprisingly little agreement as to just what sort of pecking or other form of behavior might constitute an aggressive response in young precocial birds. Some investigators have regarded any intersubject pecking as aggressive (ducklings and quail chicks: Eiserer, Emerling, Scardina, & Hoffman, 1976); others have restricted attention to pecks that cause the withdrawal of the opponent (ducklings: Hoffman, Boskoff, Eiserer, & Klein, 1975), whereas still others have concentrated on the locus of pecking (chicks: Rajecki, Ivins, & Rein, 1976).

However, it may be premature to categorize any activity on the part of developing birds as aggressive without a better knowledge of the role of organismic and environmental factors in such behavior or a fuller understanding of the mutual influence between birds engaged in particular response types. Further, although seminal sources have suggested that certain patterns of agonistic behavior emerge at different points in the development of fowl (e.g., Guhl, 1958; Kruijt, 1964), detailed information concerning the ontogeny of such responses is necessary before a taxonomy of components can be established. Therefore, the research reported here was undertaken to identify certain biological, maturational, and experiential influences on the capacity for aggressive social behavior among broodmates. The aim was to compare and contrast particular response types as possible components of aggressive behavior in young fowl.

Method

Design

The design of this longitudinal study permitted an assessment of the influence of particular factors on discrete components of chicks' social behavior. Earlier reports indicated that sex is a strong determinant of differential status between birds (Wood-Gush, 1971), so pairs consisting of a female and a male were tested. In supplemental tests, same-sex pairs were observed for aggression. Other studies of young chickens indicated that in encounters involving social pecking, there is a kind of "prior resident" or "home-cage" advantage. That is, birds tested in the home cage (or in a situation containing some feature of the home cage) generally have an edge over birds introduced to that home cage (Rajecki, Grams, Stursa, & Nerenz, 1978; Rajecki, Lamb, & Suomi, 1978; Rajecki, Nerenz, & Rein, 1978). Therefore, a "home–away" distinction was included in the current design. Further, it is clear that the physical dimensions of the test area have an influence on the likelihood of aggression in fowl, with less aggression seen in more cramped places (Hughes & Wood-Gush, 1977). Accordingly, chicks were reared in relatively large or small cages.

Finally, a recent report shows that intersubject pecking between pairmates can be promoted by repeatedly separating and reuniting cagemates for day-long periods (Rajecki, Lamb, & Soomi, 1978), so the current subjects were tested in at least 10 different reunions (following a period of physical separation) over the first 3 weeks after hatching. In sum, the basic design was a completely crossed $2 \times 2 \times 2$ ($\times 10$) factorial representing sex, the home–away distinction, cage size, and a number of repeated measures. Records were kept of a variety of responses.

In addition to observing the influence of the experimental conditions on social responses of developing chicks, the covariance of given components was assessed to provide further information on the similarities and differences between components.

Subjects

Subjects were 84 cockerels and 84 pullets of the White Leghorn strain, received on the day of hatching from the Sunnyside Hatchery in Oregon,

Wisconsin. The sex of the chicks had been determined at the hatchery by professional poultrymen using a method of cloacal extrusion, and sex was reestimated in the laboratory when the animals were 3 to 4 weeks of age by an examination of comb size and color. The two methods of determining sex agreed in 92% of the cases of 3-week-old birds and in 97% of the cases of 4-week-old birds, so the original method was used to classify subjects. Birds were housed in mixed-sex pairs and were marked with a felt pen for identification.

Large cages. Thirty-six pairs of chicks were assigned to 46 × 46 × 61 cm metal cages, each continuously illuminated and heated to 32–35 °C by a shaded 150-W lamp installed outside the wire mesh door. After several days the original bulbs were replaced by 40-W lamps that produced a midcage temperature of 24–26 °C. Each cage was also equipped with a plastic or metal trough for food (Purina chick starter) and a watering station consisting of an inverted quart jar and a plastic basin. A 30 × 30 cm sheet of absorbent paper (Cagesorb) was placed on the floor of the cage near the lamp and was liberally sprinkled with food prior to the arrival of the residents. The purpose of the paper was to insure that chicks would begin to peck at food particles, and to provide a warm substrate for the very young birds. Regardless of its physical condition, the original sheet of paper remained in the large cages for the duration of the experiment. These cages were arranged in racks of six in several laboratory rooms.

Small cages. Forty-eight pairs of chicks were assigned to 22.5 × 17.5 × 17.5 cm metal cages which contained two 5-cm petri dishes covered with wire netting, one for water and one for chick starter. Each cage was continuously illuminated and was heated to 34 °C by a 40-W bulb outside the mesh wall. After several days the original lamps were replaced with 15-W bulbs that reduced the midcage temperature to 24 °C. The small cages were arranged in racks of 12 in a single laboratory room.

Procedure

Experimental conditions. The chicks were delivered to the laboratory in large groups in separate cartons of cockerels and pullets. They were assigned to cages in pairs comprised of a male and a female.[1] Because the birds were to be repeatedly separated and reunited over the course of the experiment, one chick was designated the home bird, the other the away bird, and each was marked accordingly. The home bird remained in the home cage during separations, whereas the away bird was installed in a similar cage in an adjacent rack. Each away bird had its own away cage. The same bird was always the away bird, and birds were always reunited with their cagemate in the home cage. Across pairs an equal number of males and females were designated as away birds in both the large- and small-cage conditions.

Test sequence. The subjects were tested in two large batches during late spring and early summer. For a given test of a pair, the animals were separated for 24 hours and were then reunited. Since the act of returning the away bird involved handling the animal, the home bird was also handled. Both birds were removed from their respective cages at the same moment, and were simultaneously replaced in the home cage. Observations began immediately upon reunion, and continued for 5 minutes (after Rajecki, Lamb, & Suomi, 1978). Following the observation period the pair remained together for 24 hours and then underwent a series of such separation–reunion episodes until the completion of testing.

Since a given pair could be tested only every other day because of the separation period, a convenient schedule was adopted whereby half the sample was tested each and every day. That is, on the day each batch arrived, half the sample was placed in pairs in home cages, whereas the other half of the sample was immediately "separated," with the home bird placed in the home cage and the away bird placed in the away cage. These separated chicks were reunited and observed 24 hours later, at which point in time the birds that had been originally paired were separated for 24 hours. Thereafter these two subsets of the sample were alternately separated and reunited such that half the birds were observed in reunions on odd days of age (1, 3, 5, 7, and so on for those immediately separated) and half were observed on even days of age (2, 4, 6, 8, and so on for those initially paired). All observations were made between 9:00 a.m. and 1:00 p.m. local time. Testing continued in this fashion for about 3 weeks in the case of the subjects in the small cages and for about 4 weeks for the large-cage subjects. This procedure resulted in a within-subjects series of 10 and 14 observations per pair in the small and large cages, respectively. Although we wished to maximize the number of tests in order to detect effects for the variables under scrutiny, the testing in the small cages was terminated when the birds outgrew the units, and large-cage testing ceased when these cages were needed for a new batch of chicks that had been scheduled for delivery on a certain date.

Dependent Measures

Responses during a test were recorded by two observers, each responsible for a single bird. Eight

[1] It should be noted that the physical assignment of the birds to conditions was done by volunteers who had no other connection with the project, and the record of those assignments was not viewed by any observer until the completion of all testing for a given batch. Accordingly, at least during the early phase of this longitudinal study, an observer was blind to the sex of his or her subject (although observers were obviously aware of the birds' cage size and of whether their subject was a home or away bird). By about two weeks of age birds began to show signs of sexual dimorphism.

dependent measures were employed. Four of these measures were based on the locus of subjects' pecks and included pecks at the head, body, or feet of the testmate, or at any feature of the test unit. Discrete pecks were recorded by pressing corresponding buttons on hand-held panels that were connected to a multichannel event recorder.

A fifth response was aggressive leaping which consisted of a hop or a very rapid charging motion toward the testmate, with the leaping bird's wings flapping (cf. Kruijt, 1964, Figures 1 and 7; and the descriptions of sparring by Dawson & Siegel, 1967; and Ratner, 1965). These responses very often ended with the subject colliding with the testmate or landing with one or both feet on some part of the testmate. Each discrete leap was recorded with the press of a button.

Two other responses were recorded to measure states of disturbance on the part of the subjects (after Rajecki, Suomi, Scott, & Campbell, 1977). The first of these was the distress call, which is a long, loud note that is accompanied by the opening of the mandibles. Discrete calls were recorded. The other disturbance reaction was labeled *cage pushing*, in which a bird appeared to be motivated to escape the test situation by pushing with its beak at the walls of the cage (as distinct from pecking) or by trying to wriggle through the gaps in the mesh front. The button representing this response was pressed for the duration of an episode of cage pushing. The recording chart on which the responses were recorded was calibrated in 2-sec intervals, thus cage pushing will be discussed in terms of a time sample of 2-sec intervals per test in which the response was observed. On this index, maximum score per test is 150.

An eighth response was termed *immobility*, in which a bird rested on its breast feathers and held its eyes closed for at least several seconds. For this response, as for cage pushing, a time sample of 2-second intervals was obtained.[2]

Supplemental Tests in the Large Cages

As testing proceeded, casual observations indicated a decline in head pecking over days, and an inverted-U pattern for aggressive leaping (and see Results). These changes could be interpreted in a number of ways, so an additional test was proposed that might help evaluate competing accounts for the time-dependent shifts in responding. Supplemental tests of 14 pairs of birds[3] housed in the large cages took place after the final routine reunion. These birds were tested with strangers to determine if they would react in a xenophobic fashion (cf. Rajecki, Kidd, & Ivins, 1976; Rajecki, Ivins, & Kidd, 1977). Subsequent to the regular reunion on Days 27–28, normal procedures were followed whereby cagemates were allowed to remain together for 24 hours and were then separated for 24 hours. A 15th test of these birds was conducted at the end of this final day-long separation, but birds were not reunited with their cagemates. Rather, they were confronted with a same-sex bird from some other cage. A male bird that was an away bird was placed in the home cage of a home male, and the same procedure was followed for females. Seven pairs of male strangers and 7 pairs of female strangers were observed. Test procedures were identical in every way to those employed routinely.

Results

Subject Losses

Thirty-six pairs of chicks were assigned to the large cages, but 3 pairs did not survive the experiment. Of the remaining 33 pairs, 17 had males as the home bird and the rest had females as the home bird. Of the 48 pairs of birds assigned to the small cages, 2 pairs did not survive, thus in 24 of the remaining small-cage pairs the female was the home bird.

The small cages provided suboptimal conditions for the locomotor development of chicks. By the end of the third week, 16 of the 46 cages contained lame birds. Of these, 11 were male and 5 were female. The analyses of variance reported below were computed twice, once with the lame birds' scores included and a second time with these pairs

---

[2] Interobserver agreement using push-button panels is not problematic for experienced observers (see Rajecki, Ivins, & Rein, 1976), but new personnel were involved in this project, so reliability was checked. Observations seemed more difficult in the smaller cages, so all reliability estimates were made with extraexperimental birds in the small units. On several occasions pairs of observers watched the same bird and recorded its responses covertly. Average agreement on these occasions generally proved satisfactory for head pecks ($M = .95$, range $= .88$ to 1.00), body pecks ($M = .84$, range $= .67$ to 1.00), cage pecks ($M = .95$, range $= .88$ to 1.00), distress calls ($M = .91$, range $= .79$ to 1.00), and aggressive leaps ($M = .86$, range $= .78$ to .93). Cage pushing and foot pecking never occurred during reliability checks, but we have no reason to believe that observers were any less reliable on these measures than on the others. As a final step to insure accuracy during tests, observers instructed one another to record responses on occasions when a particular observer had his or her view of a subject blocked by obstructions such as the large water fount in the larger cages.

[3] The decision to conduct the supplemental tests was made at a time when the 14 pairs noted were the only birds remaining in the laboratory.

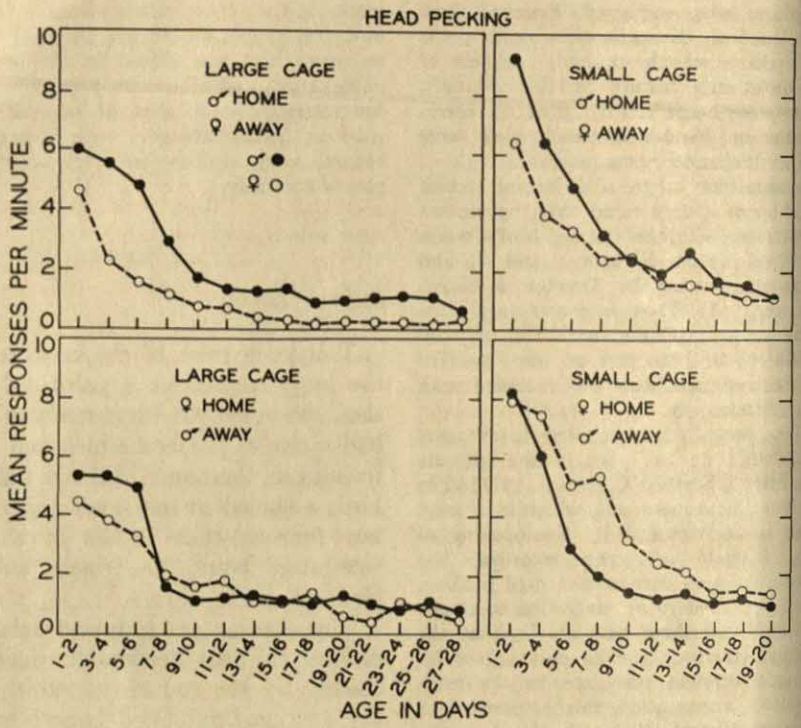

Figure 1. Head pecks per minute as a function of experimental conditions.

excluded. The two versions of each analysis were identical with respect to the direction and significance levels of results, so in this section the data from the complete sample are reported.

Analyses of Variance

Each response type was analyzed separately in terms of the $2 \times 2 \times 2$ ($\times 10$) design outlined in the method section. The birds in the large cages were tested on several more occasions than were the small-cage birds, but for purposes of comparison, only the first 10 test days of large-cage birds were contrasted with the 10 tests of birds in small cages. However, for clarity, all 14 tests of the former subjects are plotted in the figures to follow, where it can be seen that there were no substantial changes in trends established by the tenth test.

In these (and subsequent) analyses the scores for birds tested on Day 1 and Day 2 were combined, since these days represented the first test for both subsets of subjects. This combinaiton procedure was carried out for Day 3 and Day 4 scores (second test, respectively), Day 5 and Day 6 scores (third test, respectively), and so on for the remaining test days. The average scores on these combined test days are plotted in terms of entries for Day 1–2, Day 3–4, and so on, in the figures below.

Finally, the score of the individual bird was considered the unit of analysis, as this was the only way to preserve the distinction between the sexes, and the home–away distinction. However, mutual influence within pairs is of interest and will be considered in the section on correlational analyses.

Head pecking. The average numbers of head pecks per minute are shown in Figure 1. Overall, there were more head pecks in the small cages than in the large cages, $F(1, 150) = 17.55$, $p < .01$, but this difference attenuated later in testing as indicated by a Cage Size × Days interaction, $F(9, 1350) = 3.10$, $p < .01$.

Another clear finding is that home birds gave more head pecks than away birds, $F(1, 150) = 10.94$, $p < .01$. This home–away effect was not influenced by cage size, as indi-

cated by an insignificant interaction between these variables, $F(1, 150) = .92$, *ns*, and sex had little impact on the home–away distinctions, as revealed by an insignificant Sex × Home–Away interaction, $F(1, 150) = 1.02$, *ns*.

On head pecking the sexes were not clearly different overall, $F(1, 150) = 2.87$, $p > .05$. There was, however, an interesting Sex × Cage Size interaction, $F(1, 150) = 4.02$, $p < .05$, indicating that males enjoyed more of an advantage in the large cages than in the small cages. Further, holding everything else equal, a Sex × Days interaction indicated that males had an advantage early in the test sequence, but less so later on, $F(9, 1350) = 2.37$, $p < .05$.

Finally, there was a general decline in head pecking over days, $F(9, 1350) = 79.02$, $p < .01$.

Body pecking. Body pecks per minute are shown in Figure 2. Neither cage size, $F(1, 150) = .51$, *ns*, nor sex, $F(1, 150) = .14$, *ns*, had an influence on this response type. However, as in the case of head pecking, there was a clear influence for the home–away distinction, with home birds of either sex having an advantage, $F(1, 150) = 8.39$, $p < .01$. There were no interactions between any of the between-subjects factors of cage size, sex, and home–away status.

There were marked changes in the rate of body pecking over days, $F(9, 1350) = 21.46$, $p < .01$, and a Cage Size × Days interaction indicated that this response type peaked sooner in the large cages than in the small ones, $F(9, 1350) = 2.11$, $p < .05$. Finally, a Home–Away × Days interaction supports the impression that there was a decline in the home-cage advantage over the days of testing, $F(9, 1350) = 2.47$, $p < .05$.

Foot pecking. Foot pecks were rare, relative to pecks at other places. The grand per-minute means for head, body, and cage pecks were 2.61, 1.85, and 8.88, respectively, compared to a grand mean of .35 for foot pecks.

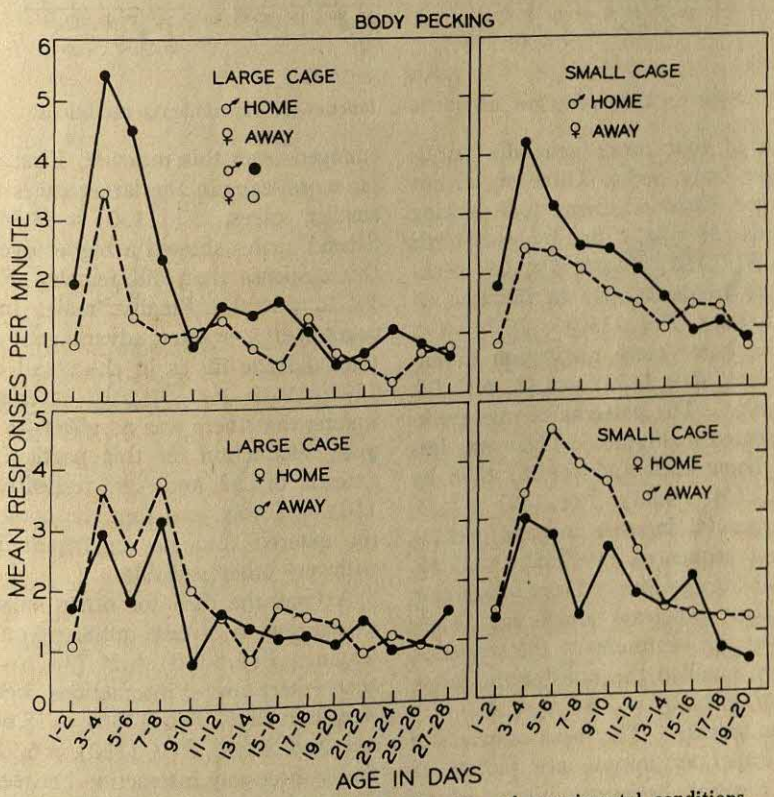

Figure 2. Body pecks per minute as a function of experimental conditions.

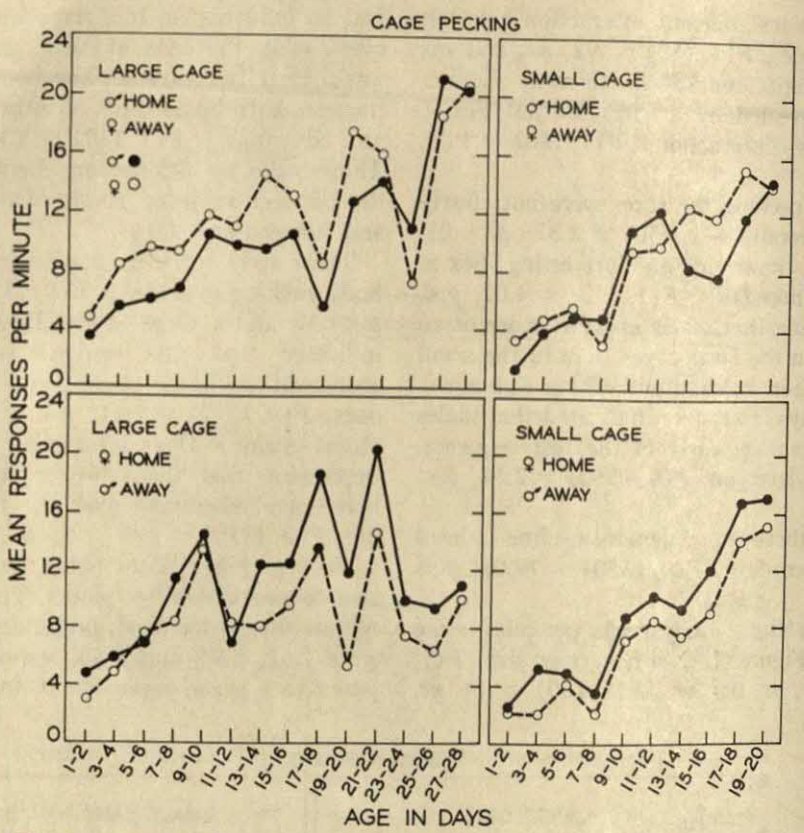

Figure 3. Cage pecks per minute as a function of experimental conditions.

The pattern of foot pecks generally paralleled that for body pecks. Three significant effects emerged. There was more foot pecking by home birds ($M = .41$) than by away birds ($M = .29$), $F(1, 150) = 5.70$, $p < .05$; pecking was more frequent early in the test sequence than later, $F(9, 1350) = 20.74$, $p < .01$; and the home–away distinction diminished over days, $F(9, 1350) = 3.18$, $p < .05$.

Cage pecking. The patterns of cage pecking are presented in Figure 3. There was less pecking by home birds ($M = 7.88$) than by away birds, ($M = 9.88$), $F(1, 150) = 4.33$, $p < .05$; a general increase in cage pecking over the test sequence, $F(9, 1350) = 17.35$, $p < .01$; and a Cage Size × Days interaction indicated that whereas small-cage birds pecked less at the beginning of the sequence, later on they equalled the rates of the large-cage birds, $F(9, 1350) = 2.84$, $p < .01$.

Aggressive leaping. The mean numbers of aggressive leaps per minute are plotted in Figure 4. Several between-subjects effects emerged from this measure. First, there were far more leaps in the larger cages than in the smaller cages, $F(1, 150) = 83.34$, $p < .01$. Second, males showed a higher overall rate of this response than did females, $F(1, 150) = 15.70$, $p < .01$. Finally, males in the large cages had a greater advantage over females than did the males in the small cages, $F(1, 150) = 9.32$, $p < .01$. Also interesting is the finding that there was no effect for the home–away distinction on this particular measure (means of .32 and .29, respectively), $F(1, 150) = .50$, *ns*, and that the home–away factor entered into no significant interactions with any other variable.

As was the case for other measures, days of age had a strong influence on aggressive leaping, $F(9, 1350) = 29.73$, $p < .01$. Further, there were interactions between cage size and days, $F(9, 1350) = 18.60$, $p < .01$, sex and days, $F(9, 1350) = 6.91$, $p < .01$, and a three-way interaction between cage size, sex, and days, $F(9, 1350) = 3.83$, $p < .01$.

These interactions mean that the differences between the sexes were more evident later in the test sequence than in early tests and that large-cage males had a longer lasting advantage over females than did small-cage males.

Other response types. The remaining responses were rarely observed. Scores on the immobility measure could range up to 150 per test, but near-zero rates emerged, with a grand mean for immobility of .12. The cage push reaction was also quite infrequent, with a grand mean of 1.35 out of a possible 150 per test. Therefore, whereas some significant effects emerged from these two measures, they do not bring much clarification to the issues at hand, and we hesitate to place strong interpretation on these contrasts because of their basis in such small numbers.

Distress vocalizations were also relatively infrequent, with a grand mean of .18. That is, during any given minute of testing, an observer was 76 times more likely to see some kind of peck than to hear a distress call. Although we have reservations about strong interpretations based on this overall low rate, it is perhaps worth noting that there was a general decline in distress calls per minute from the first day ($M = .50$) to the last day of testing ($M = .02$), $F(9, 1350) = 2.64$, $p < .01$.

Correlational Analyses

Correlations between pairmates were computed for selected measures on each day of testing. Large and small cage data were treated separately. The results of these analyses are shown in Figure 5, where conven-

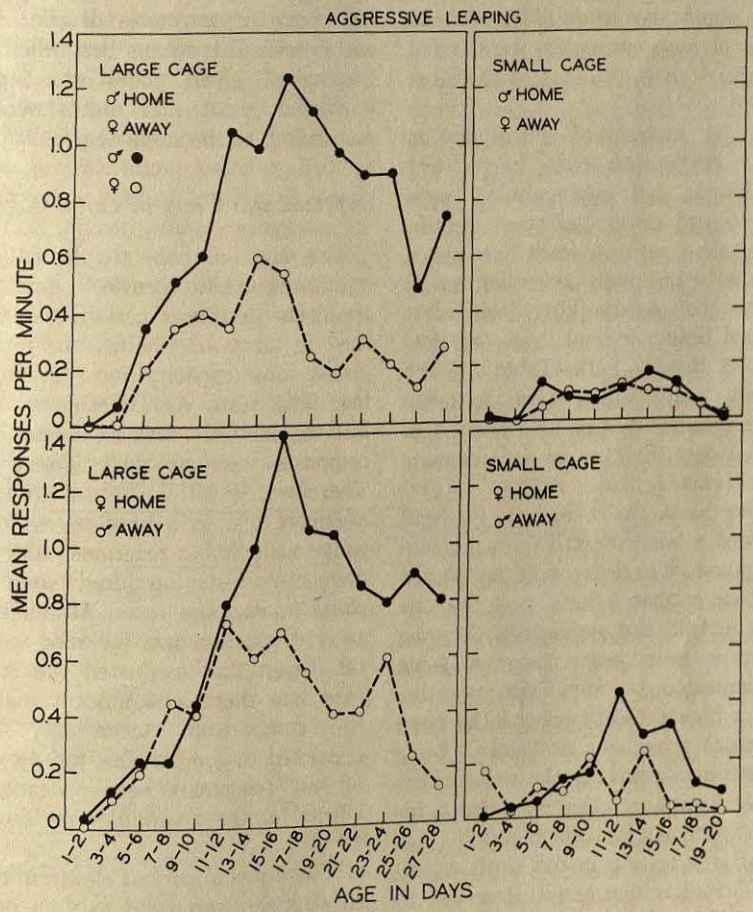

Figure 4. Aggressive leaps per minute as a function of experimental conditions.

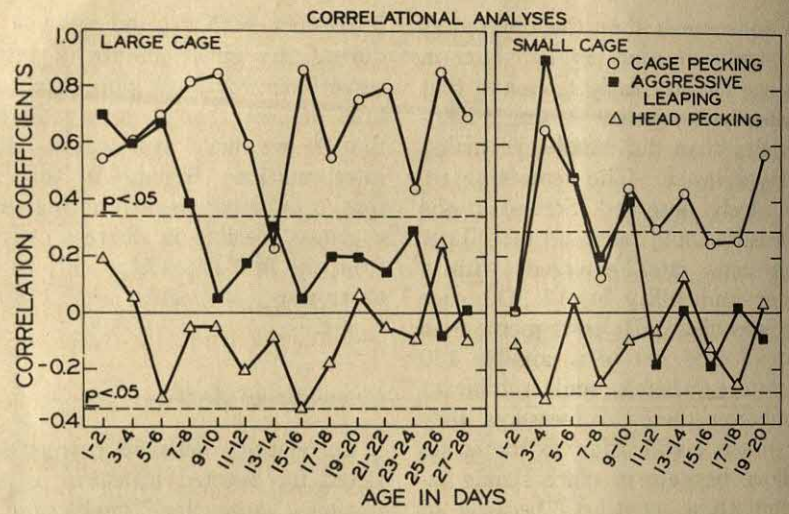

Figure 5. Correlation coefficients showing the relationship between pairs of birds on selected response types.

tional (.05) significance levels are also depicted. These significance levels differ over the two cage sizes because more pairs were tested in the small cages ($n = 46$) than in the large cages ($n = 33$).

There is a fair amount of consistency in the patterns of coefficients across the two test units. Correlations for cage pecking were mostly positive and stable, and were significantly greater than zero on many test days. This pattern is in line with an earlier report on the matching of cage pecking during this part of chicks' developmental span (cf. Rajecki, Lamb, & Suomi, 1978, Table 2). We interpret these positive correlations to mean that the cage pecking by one bird elicited or facilitated the cage pecking of its testmate (cf. Rajecki, Ivins, & Kidd, 1977).

On the other hand, the coefficients for head pecking showed a weak negative relationship for this response. The interpretation placed on this pattern is that a head peck by one bird at another did not necessarily elicit or facilitate return head pecks, and on some occasions (indicated by significant negative coefficients) a high rate of pecks to the head precluded return pecks to that locus.

In further contrast to both the patterns for cage and head pecking, the coefficients for aggressive leaping suggest that initially (or relatively early in testing in the small cages) such leaps elicited return leaps. However, as reference to Figure 4 shows, as leaps per test increase, the positive relationship between the leap rates of testmates deteriorated to zero and below. This means that when the rate of leaping of given males was highest, their particular female test mates were no longer responding to the same degree.

Supplemental Tests in Large Cages

The purpose of the supplemental tests with strangers was to provide some information about the decline in certain response rates, at least in terms of whether the birds still possessed some capacity for aggressive responding. The tests with strangers followed the last regular tests with cagemates, when many responses were at their lowest recent ebb. Therefore, it will be useful to use the final cagemate test as a baseline against which to gauge xenophobic reactions. Indeed, the supplemental tests produced some interesting shifts in response rates. Although the home-away distinction was included in the statistical design that evaluated the results, in no case was there a significant main effect for this comparison. Accordingly, attention is restricted to comparisons for sex and for type of test (cagemate versus stranger). Certain effects for these variables are shown in Table 1.

There was a marked elevation of head pecks at strangers compared to such pecks at cagemates during the last regular tests, $F(1, 24)$

$= 9.00$, $p < .01$. The sexes did not differ on this measure, $F(1, 24) = 2.18$, *ns*, nor was there an interaction between sex and type of test, $F(1, 24) = 1.54$, *ns*.

Effects for body or foot pecking did not emerge, but there was a strong effect for tests on the cage peck measure. Table 1 shows that cage pecking was much less frequent among strangers than among cagemates, $F(1, 24) = 12.15$, $p < .01$, with males and females affected across tests about equally, $F(1, 24) = .77$, *ns*.

On the other hand, sex had a very strong influence on aggressive leaping, with males engaging in this behavior more than females overall, $F(1, 24) = 28.19$, $p < .01$. As was the case with head pecking, there was more leaping during tests of strangers than during tests of cagemates, $F(1, 24) = 11.19$, $p < .01$, but interestingly enough, it can be seen in Table 1 that the cagemate–stranger difference is due entirely to the behavior of the males, $F(1, 24) = 10.56$, $p < .01$. In fact, comparisons between Table 1 and Figure 4 show that males' average rate of leaping at unfamiliar males was about twice as high as the highest average rate of leaping at female cagemates. This indicates that leaping was indeed an aggressive response and not strictly a sexual response directed at the opposite sex.

The distress call and immobility measures revealed no significant effects, but there was an interesting interaction between sex and test on the cage push measure. When tested with their familiar female cagemates, males showed 0 scoring units (see Method) on this index, but their scores rose to an average of 1.14 when tested with unfamiliar males. To the contrary, females showed an average score of 4.21 when tested with familiar males and only .43 such units when confronted with unfamiliar females, $F(1, 24) = 5.03$, $p < .05$.

Table 1
Average Responses per Minute in the Last Regular Tests With Cagemates (Mixed-Sex Pairs) and the Supplemental Tests With Strangers (Same-Sex Pairs)

Sex	Test	
	Cagemate	Stranger
	Head pecking	
Male	.31	1.07
Female	.10	.41
	Cage pecking	
Male	17.86	.84
Female	17.46	7.29
	Aggressive leaping	
Male	.56	2.54
Female	.14	.17

Discussion

Note should be made of the fact that the behavioral profiles just reported emerged under conditions of multiple separations and reunions of female and male pairmates. There is little doubt that birds reared under other circumstances, sexual combinations, or numbers might exhibit very different patterns. Previous evidence indicated that, compared to animals never separated, the multiple separation procedure enhances social behavior over this age range (see Rajecki, Lamb, & Suomi, 1978), and this was precisely why the technique was used here. The separation technique proved quite useful for demonstrating the capacity and forms of social behavior in developing fowl, which was the aim of the study.

In some cases, patterns of behavior across the large and small cages were vastly different. In order to bring organization to these and other complicated results, we will begin with the findings from the large cages, and then take up the small-cage data.

Behavior in Large Cages

The behavior of the birds in the large cages clearly indicates that in studying the development of aggressiveness in such species, different forms of physical contact between individuals cannot be viewed as equivalent. That is, response types such as head pecking, body pecking, foot pecking, and leaping are not interchangeable indexes of "aggression" because they seem governed by separable influences or factors. By this we do not mean merely that certain response types are more or less likely at given points in maturation. Rather, we mean that when they emerge or

reach peak rates, given responses seem differentially mediated by internal or external factors.

At one extreme, aggressive leaping in the large cages appears to have been independent of the environmental factor represented by the home–away distinction. Regardless of whether males were home or away, they began leaping (on average) at the same point in the developmental span and reached the same peak rate on the same test day. Also interesting in this respect are the leaping responses of the females. On average, both home and away females initially matched the male rates but then peaked at the same level on the same day.

At the other extreme, sex had little effect on body pecking compared with its influence on leaping. When rates of body pecking peaked, it was the home bird that showed the highest rate, regardless of sex (and a similar pattern emerged for foot pecking).

Further, it seems possible to draw distinctions between leaping and head pecking. Males had a general advantage over females in head pecking at the point of peak response rate, but this sex difference did not conform to the profile of the sex difference for leaping. In leaping, males established an advantage and then kept it (so to speak), whereas in head pecking the males had an advantage, then lost it. Finally, head pecking is different from body pecking, since at the point of maximum head peck rates in the large cages, the biological factor of sex outweighed the environmental factor that was based on the home–away distinction.

The components of social behavior are also distinguished from one another by the correlations within response types. The correlational analyses presented in Figure 5 demonstrate pronounced differences across response categories. These analyses indicate that cage pecks were matched between birds, but that head pecks were not. Interestingly, leaps were matched early in the test sequence but not later. The interpretation we place on these different patterns is that different motivational factors mediate such responses. A peck to the head may or may not reflect an aggressive disposition on the part of the pecking bird, but it does not seem to serve as an occasion for retaliatory pecks on the part of the target (cf. Rajecki, Ivins, & Rein, 1976). On the other hand, an aggressive leap was likely to elicit a leap in return,[4] up to a point in testing. We suspect that that point was reached when the females became submissive. This suspicion seems borne out by the reaction of males to chickens that were not submissive; that is, their opponents in the male–male supplemental tests. These supplemental tests produced the highest rates of leaping seen in the study and revealed a very close match in leap rates between such willing birds, $r(12) = .98$, $p < .01$.

This allusion to the supplemental tests brings us to another distinction between leaping and head pecking. The tests of female strangers revealed very little leaping, and we suggest (as noted earlier) that this was so because they had learned, on the basis of their experience with males, to inhibit leaps in the presence of a testmate. However, if females were subdued with respect to leaping, they were much less so with respect to head pecking. Like their male counterparts, females showed a fourfold increase in head pecking in tests of strangers, as compared with tests of cagemates.

Behavior in Small Cages

A number of reports (cf. Craig & Bhagwat, 1974; Craig, Biswas, & Guhl, 1969; Hughes & Wood-Gush, 1977) indicate that fowl kept in close confinement are less likely to show aggressive behavior than are birds reared in more spacious units. Hughes and Wood-Gush (1977) account for this difference by hypothesizing that aggression is triggered by the event of birds coming into proximity rather than by the condition of being in continuous proximity. Indeed, the data from the small cages are in strong support of the hy-

[4] It is worth reporting that head pecks are not correlated with leaps. Correlation coefficients were computed to determine the relationship between male head pecks and female leaps and between female head pecks and male leaps. This analysis yielded 48 coefficients from the regular daily tests in the large and small cages. These coefficients ranged from −.27 to .27, with none significantly different from zero.

pothesis that close confinement dampens or otherwise influences aggressive responding. The first indication of this is that males in small cages had no advantage over females on head pecking; in these units the home bird had the edge regardless of sex. There was also a home-cage advantage in body pecking, as was seen in the larger units.

However, the most dramatic difference across the two cage sizes was on the aggressive leaping index, with leaps in the small cages being far less frequent (see Figure 4). There are two ways to account for this difference. First, the relative absence of leaping in the small units may be in line with the Hughes and Wood-Gush (1977) notion that birds continuously in proximity are not in the proper condition to be stimulated to aggress. On the other hand, at present we cannot rule out the argument that the very dimensions of the small cages may have reduced leaping, whatever the disposition of the inhabitants.

The distinction between leap and head peck rates in the small cages is, however, noteworthy with respect to the motivational bases of such responses. While leaping was somehow limited by confinement, head pecking under these conditions was initially higher than in the large cages. Of course, the peak rates for these responses occurred at different points in development, but the differential effect of the small units on pecking and leaping further points to distinctions between components of agonistic behavior in fowl.

Issue Involvement Can Increase or Decrease Persuasion by Enhancing Message-Relevant Cognitive Responses

Richard E. Petty
University of Missouri—Columbia

John T. Cacioppo
University of Iowa

Two experiments were conducted to test the hypothesis that high issue involvement enhances thinking about the content of a persuasive communication. Experiment 1 varied involvement and the direction of a message (proattitudinal or counterattitudinal). Increasing involvement enhanced persuasion for the proattitudinal but reduced persuasion for the counterattitudinal advocacy. Experiment 2 again varied involvement, but both messages took a counterattitudinal position. One message employed compelling arguments and elicited primarily favorable thoughts, whereas the other employed weak arguments and elicited primarily counterarguments. Increasing involvement enhanced persuasion for the strong message but reduced persuasion for the weak one. Together the experiments provide support for the view that high involvement with an issue enhances message processing and therefore can result in either increased or decreased acceptance.

Persuasion researchers have recognized for some time that it is easier to demonstrate attitude change in the laboratory than in the field. One prominently mentioned explanation for this observation is that the advocacies employed in laboratory investigations are of considerably lower "involvement" than the advocacies encountered in the real world (Hovland, 1959). Greater involvement with an issue is presumably related to greater resistance to persuasion (cf. Triandis, 1971). The major goal of the present paper is to present and test a "cognitive response" (Greenwald, 1968; Petty, Ostrom, & Brock, in press) interpretation of involvement effects holding that increasing involvement with an issue increases one's motivation to process information relevant to the issue and can lead to either increased or decreased persuasion.

We are grateful to Chuck LaJuenesse, Colleen Holt, Greg Bistline, and Michael Bryant for help in collecting and coding the data of Experiment 2, and to the University of Missouri Research Council for financial support.

Requests for reprints should be sent to Richard E. Petty, Department of Psychology, 210 McAlester Hall, University of Missouri, Columbia, Missouri 65211.

Before presenting the model in more detail, it is necessary to note that attitude researchers have distinguished between two different types of involvement that can affect susceptibility to influence. One kind of involvement concerns the extent to which the attitudinal *issue* under consideration is of personal importance, whereas a second concerns the extent to which the particular attitudinal *response* adopted is of personal importance to the individual. The first type of importance, which is the type under investigation here, has been called "issue involvement" (Kiesler, Collins, & Miller, 1969), "ego-involvement" (Rhine & Severance, 1970; Sherif, Sherif, & Nebergall, 1965), and "personal involvement" (Apsler & Sears, 1968; Sherif, Kelly, Rodgers, Sarup, & Tittler, 1973). Also, Halverson & Pallak (1978) and Madsen (1978) have argued that typical manipulations of "commitment" (cf. Kiesler, 1971) elevate involvement with an issue.

The second type of involvement is often referred to as "response involvement" (Zimbardo, 1960) or "task involvement" (Sherif & Hovland, 1961). In this second kind of involvement, the attitudinal issue is not particularly important to the person, but adopt-

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3710-1915$00.75

ing a position that will maximize the immediate situational rewards is. Thus in some cases response involvement will lead to increased influence (e.g., Zimbardo, 1960) and in some cases decreased influence (e.g., Freedman, 1964), depending upon which position the rewards favor.

The focus of this paper is on the mechanism mediating the effects of high issue involvement. High issue involvement occurs when an issue has "intrinsic importance" (Sherif & Hovland, 1961, p. 197), or "personal meaning" (Sherif et al., 1973, p. 311), when people expect the issue "to have significant consequences for their own lives" (Apsler & Sears, 1968, p. 162), and when concerns about immediate situational rewards are "dwarfed by outcomes connected with the topic itself" (Cialdini, Levy, Herman, Kozlowski, & Petty, 1976, p. 664). Most of the early research indicated that increased issue involvement was associated with increased resistance to persuasion (e.g., Miller, 1965; Sherif & Hovland, 1961). The most prominently mentioned explanation for this finding was derived from social judgment theory (Sherif et al., 1965). The notion was that on any given issue, highly involved persons should exhibit more negative evaluations of a communication because high involvement is associated with an extended "latitude of rejection" (the attitudinal positions that a person finds unacceptable). Thus, incoming messages on high involvement issues would have an enhanced probability of being rejected because they were more likely to fall within the unacceptable range of a person's implicit attitude continuum (cf. Eagly & Manis, 1966).

Contrary to social judgment theory, which seems always to predict greater resistance with increased issue involvement, some investigators have found increased involvement to be associated with greater influence. For example, Eagly (1967) presented subjects with information about either themselves (high involvement) or another person (low involvement) that was discrepant in either a favorable or an unfavorable direction from their initial attitudes. She found that although high involvement subjects changed less than low involvement subjects when unfavorable information was provided, the former exhibited more change when favorable information was provided. Similarly, Pallak, Mueller, Dollar, & Pallak (1972) presented subjects who were either publicly committed (high involvement) or privately committed (low involvement) to their initial attitudes with information that either contradicted their opinions or was consistent but more extreme. They found that involvement increased resistance to the countercommunication but facilitated change toward the position advocated by the extreme consonant message. In order to account for these results, Pallak et al. (1972) suggested a modification of the original social judgment model. The new formulation was that high involvement (or commitment) increased the probability of rejecting or contrasting counterattitudinal information but increased the probability of accepting or assimilating proattitudinal information.

These same data may be explained by an alternative view holding that involvement increases the amount of thought in which subjects engage about the stimulus information. When the stimulus information is inconsistent with subjects' original attitudes, it is likely that subjects are motivated and able to generate counterarguments to the material presented. To the extent that increased involvement is associated with more thinking, increased counterargumentation and resistance to influence would be a likely result. On the other hand, when the stimulus information is consistent with subjects' original attitudes, it is likely that they are initially biased toward generating favorable cognitions. To the extent that increased involvement is associated with more thinking here, more favorable thoughts might be generated, and increased influence would result. There is already a large body of literature supporting the view that the idiosyncratic cognitive responses elicited by a communication are an important determinant of the direction and amount of attitude change produced (e.g., Brock, 1967; Cacioppo & Petty, 1979; Cook, 1969; Insko, Turnbull, & Yandell, 1974; Petty, Wells, & Brock, 1976; Tesser, 1978; etc.).

It is also important to note that there are already some suggestions in the literature that

increased involvement with a stimulus is associated with more extensive information processing. For example, Rogers, Kuiper, and Kirker (1977) had subjects rate personality adjectives in terms of their self-relevance (high involvement) or semantic, phonemic, and structural properties (low involvement). Adjectives processed under high involvement conditions were subsequently recalled best in an incidental recall test. According to Craik and Lockhart's (1972) "depth of processing" framework, enhanced recall is thought to reflect more extensive processing of the stimulus. More relevant to persuasion situations, Cialdini et al. (1976) found that subjects who expected to engage in a discussion with an opponent generated more supportive thoughts in anticipation of the discussion when the attitude issue was of high rather than low personal relevance. Finally Chaiken (Note 1) and Petty & Cacioppo (1979) have reported that subjects' message-relevant thoughts show higher correlations with message acceptance under high than under low issue involvement conditions.

Two experiments were conducted to test the cognitive response view of the effects of issue involvement. The primary goal of Experiment 1 was to replicate conceptually the Eagly (1967) and Pallak et al. (1972) attitudinal findings; measures of subject-generated cognitive responses were included also to assess the viability of the proposed reformulation of issue-involvement effects. The second experiment was designed to evaluate the two competing explanations of issue-involvement effects, namely, thought enhancement versus the revised social judgment theory formulation. Thus, an experiment was devised for which the two formulations made competing predictions.

Experiment 1

Most of the early work on issue involvement was conducted by finding existing groups that differed in the extent to which an issue was important, and thus this work was correlational in nature (see Kiesler et al., 1969, for the interpretational problems with this approach). More recent investigators have chosen to *manipulate* involvement by varying the issue between subjects (e.g., Dean, Austin, & Watts, 1971; Rhine & Severance, 1970). In other words, some subjects would receive a highly involving issue (e.g., increasing tuition), whereas others received an issue of low involvement (e.g., increasing park acreage in a distant city). A preferable procedure that keeps the communication constant across subjects was introduced by Apsler and Sears (1968) and is the method employed here. In this procedure, subjects in both high and low involvement groups receive the same communication, but high involvement subjects are led to believe that the advocated change will affect them, whereas low involvement subjects do not believe the change will have personally relevant effects. In the present study, this was accomplished by telling the college student subjects that a proposed change in university regulations regarding mixed-sex visitation hours was being made at either their university or a distant university. Pilot testing was conducted to develop proattitudinal and counterattitudinal communications. Not surprisingly, advocating more lenient regulations regarding visitation hours was found to be highly proattitudinal, and advocating stricter regulations was highly counterattitudinal. In addition, pilot testing revealed that subjects generated predominantly favorable thoughts to the proattitudinal communication and counterarguments to the counterattitudinal appeal. In Experiment 1 subjects received either a proattitudinal or a counterattitudinal advocacy under conditions of either high or low issue involvement. We predicted that increased involvement would enhance processing of the message contents. As a result of this, we expected both cognitive and affective responses to the two messages to be more extreme under high than under low involvement conditions. More specifically, increased involvement should decrease agreement with the counterattitudinal message but increase agreement with the proattitudinal communication.

Method

Procedure

Twenty-four male undergraduates at the University of Notre Dame participated in order to earn

extra credit in an introductory psychology course. The design was a 2 (High or Low Issue Involvement) × 2 (Proattitudinal or Counterattitudinal Message Direction) factorial. Subjects were tested individually. Upon arrival, subjects were informed that students in a sound engineering course had prepared the communications that were to be employed in the investigation and that in return for the use of the tapes in other research, the investigators had agreed to provide evaluations of the sound quality of the tapes. The subjects were asked to aid in this endeavor.

Subjects were informed of the topic and position of the communication they were about to hear and 60 sec later were exposed to one of two professionally taped messages. Following exposure to a 2-minute message, subjects completed the dependent variable booklets and were debriefed, thanked, and dismissed.

Independent Variables

Message direction. All subjects were exposed to a communication concerning coed visitation hours. The *proattitudinal* advocacy contended that colleges should be more lenient in allowing mixed-sex visitation. Elaborations of the following arguments were employed: (a) More lenient hours would not interfere with education, since the "Educational Examination Foundation" found no correlation between the length of visitation hours and graduate school entrance examination scores; (b) they also found no connection between visitation hours and grade point average; (c) enforcement of the morality inherent in visitation hours fails because morality is not tied to time of day; (d) since college is a period of responsible maturation, the imposition of visitation hours can be counterproductive; and (e) students are able to judge for themselves at what time a party should end. The *counterattitudinal* advocacy contended that colleges should be more strict in their visitation policies. Elaborations of the following arguments were employed: (a) Since the main purpose of going to college is to learn, university officials feel obligated to restrict weekday partying; (b) longer visitation hours have caused a trend away from Christian morals and ideals; (c) the "Educational Examination Foundation" found that the longer the visitation hours at a university, the lower the graduate school entrance examination scores obtained by its students; (d) they also found a negative correlation between visitation hours and grade point average; and (e) young students are not mature enough to handle the social pressures that accompany an increase in visitation hours.

Issue involvement. For subjects in the *high involvement* conditions, the speaker advocated that the change in visitation rules go into effect at their own university (Notre Dame). Thus all subjects would be affected personally by the proposal. In the *low involvement* conditions, the speaker advocated that the change in visitation rules go into effect at another university (Juanita Junior College). Thus, none of the subjects would be affected personally by the proposal. The messages in both involvement conditions were identical except for the words *Notre Dame* and *Juanita Junior College*.

Dependent Variables

Attitude measures. On the first page of the dependent variable booklet, subjects read: "Because your own opinion about the position advocated on the tape may influence the way you rate the quality of the tape, we would like to obtain a measure of how you feel about the views proposed by the speaker on each scale below." Two measures of opinion about visitation hours were included. First subjects rated the advocated position on four 9-point semantic differential scales (harmful–beneficial, wise–foolish, good–bad, favorable–unfavorable) that were summed to obtain a general measure of evaluation. Next, subjects responded to an 11-point Likert-type rating scale regarding their agreement with the speaker's position. On the scale, 1 indicated that the subject "did not agree at all," and 11 indicated "agree completely." The subjects' responses to the two attitude measures were converted to standard scores and were averaged for an index of communication acceptance.

Cognitive response measures. After completion of the attitude scales, subjects were given 2½ minutes to list the thoughts they had while listening to the tape (cf. Petty & Cacioppo, 1977). Twelve 8-inch (20.32 cm) horizontal lines each about 1 inch (2.54 cm) from the one above created the boxes in which subjects were to write their ideas, one per box. After recording their thoughts, subjects were instructed to rate their ideas as either + (in favor of the advocated position), − (opposed to the advocated position), or 0 (neutral or irrelevant). No independent judges were used to score subjects' thoughts, since previous research has indicated that subjects' and judges' ratings correlate highly (cf. Petty et al., 1976). After rating their thoughts, subjects completed a page of ancillary items regarding the quality of the taped communication and how involving they felt it was.

Results and Discussion

Manipulation Checks

Subjects rated the extent to which they found the communication "involving" on an 11-point scale where 11 indicated "extremely involving." Subjects in the high involvement conditions rated the message as significantly more involving ($M = 6.67$) than subjects in the low involvement conditions ($M = 4.75$), $F(1, 20) = 5.09$, $p < .03$, providing support for the effectiveness of the involvement manipulation.

Table 1
Attitudes and Cognitive Responses in Relation to Involvement and Type of Message (Pro or Counter)

Item	Counterattitudinal message		Proattitudinal message	
	Involvement		Involvement	
	Low	High	Low	High
Attitude	$-.39_a$	-1.79_b	$.62_c$	1.57_d
Counterarguments	3.00_{ac}	4.00_a	2.00_{bc}	$.67_b$
Favorable thoughts	1.33_{ab}	$.50_b$	1.17_{ab}	3.17_a

Note. Means in any given row without a common subscript are significantly different at the .05 level by the Newman–Keuls procedure.

The mean score on the standardized attitude index for subjects hearing the counterattitudinal advocacy was −1.10, which differed significantly from the mean score of 1.10 for subjects hearing the proattitudinal message, $F(1, 20) = 35.33$, $p < .001$. An average of 3.5 counterarguments was generated to the counterattitudinal message, whereas an average of only 1.3 counterarguments was generated to the proattitudinal message, $F(1, 20) = 15.09$, $p < .001$. An average of 2.2 favorable thoughts was generated to the proattitudinal message, whereas only .9 favorable thoughts were generated to the counterattitudinal message, $F(1, 20) = 3.5$, $p < .07$. The attitude and cognitive response data provide support for the notion that the two communications differed in the agreeableness of their positions.

Tests of Hypotheses

The attitude and cognitive response data are presented in Table 1. It was expected that involvement would decrease the effectiveness of the counterattitudinal message but increase the effectiveness of the proattitudinal message. A significant Involvement × Message interaction on the attitude index provided support for this hypothesis, $F(1, 20) = 10.14$, $p < .005$. A Newman–Keuls analysis revealed that increased issue involvement increased agreement with the proattitudinal message but decreased agreement with the counterattitudinal advocacy (see Table 1).

Similar Involvement × Message interactions on the cognitive response measures provided support for the information-processing interpretation of involvement effects: counterarguments $F(1, 20) = 4.36$, $p < .05$; favorable thoughts $F(1, 20) = 4.42$, $p < .05$. Newman–Keuls analyses of these interactions (Table 1) revealed that under high involvement subjects generated more favorable thoughts and fewer counterarguments to the proattitudinal advocacy than to the counterattitudinal one; under low involvement, however, neither the number of favorable thoughts nor the number of counterarguments was affected by message direction. Surprisingly, there was a tendency for subjects hearing the proattitudinal message under low involvement to generate more counterarguments than did subjects hearing the same message under high involvement. Postexperimental interviews with subjects suggested that this effect may have resulted from subjects' jealousy over having such a desirable effect (leniency in visitation hours) occur at an institution other than their own.

The analyses of the several ancillary measures on tape quality revealed one significant effect. Subjects rated the speaker's voice quality as higher in the high involvement conditions than in the low, $F(1, 20) = 6.68$, $p < .05$. This effect was obtained regardless of whether the speaker advocated a proattitudinal or a counterattitudinal position and is puzzling, since both high and low involvement subjects heard identical tapes (except for the spliced insertion of the name of the appropriate university). A possible explanation for this finding may be that subjects wanted to

give the tapes higher quality ratings when they were prepared by students at their own institution than when they were prepared at another school.

Experiment 2

Although the cognitive response data from Experiment 1 provide support for the notion that increasing involvement increases the thinking that subjects engage in about an attitudinal issue, the attitude data could just as easily be explained by the revised social judgment formulation. Thus, subjects may have assimilated the proattitudinal information, producing acceptance, and contrasted the counterattitudinal information, producing resistance. According to the Pallak et al. (1972) formulation, the key determinant of whether involvement will facilitate or hinder persuasion is the extent to which the information provided appears to contradict the subject's initial position. When the information advocates a position opposite to that of the subject, involvement will decrease persuasion, but involvement "facilitates change toward a more extreme attitude in response to appeals which do not explicitly reject one's own position" (Pallak et al., 1972, p. 434).

According to the cognitive response view espoused here, the position advocated in the communication is not as important as the nature of the thoughts elicited by the message. Two counterattitudinal communications were constructed specifically for Experiment 2. Both messages argued that seniors be required to pass a comprehensive exam in their declared major before being granted a degree. Previous work has indicated that this position is strongly counterattitudinal for most college students (Petty & Cacioppo, 1977). The messages differed, however, in their presentation of eight key arguments. One message was designed to contain points that were logically sound, defensible, and compelling. The arguments in this message were selected from a pool that elicited predominantly favorable thoughts in a pretest. A second message was designed to be more open to refutation and skepticism. The arguments in this message were selected from a pool that elicited predominantly counterarguments in a pretest.

Given that the messages advocated an identical counterattitudinal position, but differed in the quality of the arguments used to support that position, it becomes possible to evaluate the two explanations of the effects of issue involvement. The modified social judgment formulation, as outlined by Pallak et al. (1972), predicts that increased issue involvement will produce decreased persuasion for both messages, since each message adopts an identical position in opposition to the subjects.[1]

The cognitive response hypothesis, on the other hand, predicts that increased issue involvement will be associated with decreased persuasion only for the message containing "counterarguable" arguments. For the message containing the compelling and difficult-to-counterargue arguments, increased involvement should be associated with increased persuasion. In other words, increased involvement motivates subjects to process the information contained in the communications more carefully. Thus, although high involvement may initially increase a subject's motivation to reject a counterattitudinal advocacy, subjects should ultimately better recognize the flaws in the weak communication and the virtues in the strong one.

In sum, the following predictions were made for Experiment 2. More counterarguments would be generated to the weak than to the strong communication, but more favorable thoughts would be generated to the strong message. There would be significant Arguments × Involvement interactions on the attitude and cognitive response measures. As in Experiment 1, it was predicted that both cognitive and affective responses to the two messages would be more polarized under high than under low involvement conditions.

---

[1] Alternatively, it might be predicted that involvement would increase resistance more for the message containing the compelling rather than the weak arguments, since this message might be viewed as taking a stronger stand against one's own position (Kleinhesselink & Edwards, 1975). In any case, the modified social judgment formulation expects increased involvement to be associated with decreased persuasion for both messages.

Method

Procedure

Seventy-two male and female undergraduates at the University of Missouri participated in order to earn extra credit in an introductory psychology course. The design was a 2 (High or Low Issue Involvement) × 2 (Strong or Weak Argument Quality) factorial. Subjects were run in groups of 4 to 12 in cubicles constructed so that no subject could have visual or verbal contact with any other subject. During any one session, all four experimental conditions were run. Upon arrival at the laboratory, subjects were told that each year the psychology department assists the school of journalism in evaluating radio editorials that are sent in by colleges and universities throughout the country; their task would be to provide ratings of the quality of the editorials. Following these instructions, subjects heard one of the taped communications over headphones. After listening to the appropriate 4-minute communication and completing the dependent variable booklets, subjects were debriefed, thanked, and dismissed.

Independent Variables

Argument quality. As noted previously, all subjects heard a communication advocating that seniors be required to pass a comprehensive exam in their declared major prior to graduation. In brief, the *strong version* of the message provided evidence (statistics, relevant studies, etc.) in support of the following arguments: (a) Prestigious universities have comprehensives to maintain academic excellence, (b) institution of the exams has led to a reversal in the declining scores on standardized achievement tests, (c) graduate and professional schools show a preference for undergraduates who have passed a comprehensive exam, (d) average starting salaries are higher for graduates of schools with the exams, (e) schools with the exams attract larger and more well-known corporations to recruit students for jobs, (f) the quality of undergraduate teaching has improved at schools with the exams, (g) state legislatures would increase financial support if exams were instituted, allowing a tuition increase to be avoided, and (h) the (fictitious) National Accrediting Board of Higher Education would give the university its highest rating if the exams were instituted.

The *weak version* of the message also contained 8 arguments but relied more on quotations and opinions than on statistics and data to support the following arguments: (a) Adopting the exams would allow the university to be at the forefront of a national trend, (b) graduate students have complained that since they have to take comprehensives, undergraduates should take them also, (c) by not administering the exams, a tradition dating back to the ancient Greeks was being violated, (d) parents had written to administrators in support of the plan, (e) the exams would increase student fear and anxiety enough to promote more studying, (f) the exams would help to cut costs by eliminating the necessity for other tests that varied with instructor, (g) the exams would allow students to compare their performance with students at other schools, and (h) job prospects might be improved.

Issue involvement. Involvement was manipulated in a manner analogous to that employed in Experiment 1. For subjects in the *high involvement* conditions, the speaker advocated that the comprehensive exams be instituted at the University of Missouri (the subjects' institution), whereas for *low involvement* subjects, the speaker advocated that the exams be instituted at North Carolina State University.

Dependent Variables

The same measures were available as in Experiment 1. Subjects rated the concept "comprehensive exams" on four 9-point semantic differential scales and then responded to an 11-point Likert-type scale regarding their agreement with the speaker's position. As in Experiment 1, responses to the two attitude measures were converted to standard scores and were averaged to form the measure of communication acceptance.

Next, subjects were given 2½ minutes to list the thoughts they had while listening to the tape. Subjects also rated their thoughts with a +, −, or 0, as described for Experiment 1. In addition, some ancillary questions about the quality of the tape were completed, and subjects were asked to rate the amount of thought they engaged in about the issue. Finally, subjects were given 3 minutes to attempt to list as many message arguments as they could remember. Each booklet was rated by two judges ($r = .88$) who were blind to the involvement manipulation. An argument had to correctly summarize one of the arguments that appeared in the appropriate message to be counted. Repetitions of the same argument were not counted. Disagreements between judges were resolved through discussion.

Results

Manipulation Checks

In order to determine whether our manipulation of involvement affected the amount of message processing subjects engaged in, subjects were asked to rate on an 11-point scale (1 indicated *not very much* and 11 indicated *very much*) how much thought they put into evaluating what the speaker had to say. Subjects in the high involvement conditions reported doing more thinking about the messages ($M = 8.6$) than subjects in the low involvement cells reported ($M = 7.75$), $F(1, 68) = 2.75$, $p < .05$, one-tailed. These data support the view that the involvement manip-

ulation affected the hypothesized mediating variable. In other words, increasing the personal relevance of an advocacy affected the perceived amount of thought subjects engaged in about that advocacy.

Analyses of the attitude and cognitive response measures indicated that the manipulation of message quality was also effective. The mean score on the standardized attitude index for subjects hearing the strong arguments was .45, which differed significantly from the mean score of −.45 for subjects hearing the weak arguments, $F(1, 68) = 21.65$, $p < .001$. An average of 2.19 favorable thoughts was generated to the strong arguments, whereas only .99 were generated to the weak arguments, $F(1, 68) = 15.19$, $p < .001$. An average of 2.69 counterarguments was generated to the weak message, whereas 1.69 were generated to the strong message, $F(1, 68) = 8.36$, $p < .005$. The attitude and cognitive response data provide support for the notion that the two communications differed in the strength of their arguments.

Tests of Hypotheses

The attitude and cognitive response data are presented in Table 2. A significant Arguments × Involvement interaction on the attitude index, $F(1, 68) = 5.62$, $p < .02$, and a Newman–Keuls analysis (Table 2) provided support for the hypothesis that involvement would increase the persuasiveness of the strong arguments but would decrease the persuasiveness of the weak arguments.

Involvement × Arguments interactions on the cognitive response measures also provided support for the information-processing interpretation of involvement effects: counterarguments $F(1, 68) = 7.46$, $p < .008$; favorable thoughts $F(1, 68) = 4.35$, $p < .04$. A Newman–Keuls analysis on each of these measures (Table 2) revealed that under high involvement, subjects generated more favorable thoughts and fewer counterarguments to the strong than to the weak arguments; under low involvement, neither favorable thoughts nor counterarguments were affected by the argument quality manipulation. The Newman–Keuls analyses further demonstrated that higher involvement increased the production of counterarguments to the weak arguments and increased the production of favorable thoughts to the strong arguments.

Analyses of the ancillary measures of tape quality produced no significant differences. No significant effects were obtained on the number of arguments that subjects could recall either, although—consistent with the "depth of processing" notion—there was a slight tendency for high involvement subjects to recall more arguments ($M = 3.75$) than did low involvement subjects ($M = 3.2$), $F(1, 68) = 2.07$, $p < .15$. The interaction on this measure did not approach significance ($p > .25$).

Correlational Analyses

Table 3 presents the correlations among the attitude and cognitive response measures separately for high and low involvement subjects. The pattern of correlations indicates that message-relevant cognitive responses are better predictors of attitude change under high than

Table 2
Attitudes and Cognitive Responses in Relation to Involvement and Quality of Message Arguments

under low involvement conditions. This replicates the findings of Chaiken (Note 1) and Petty & Cacioppo (1979) and is consistent with the view that high involvement increased the importance of message processing in producing persuasion. The ability to recall message arguments did not allow any reliable prediction.[2]

Discussion

The pattern of data in both experiments provides strong support for the cognitive response view of the effects of increased issue involvement on persuasion. The results of both experiments contradicted the original social judgment theory formulation (Sherif et al., 1965), which proposed that increased involvement would invariably reduce persuasion. In addition, the results of Experiment 2 extended the Pallak et al. (1972) formulation, which limited the persuasion-facilitating effects of increased issue involvement to extreme consonant messages. Experiment 2 demonstrated that increased involvement could lead to increased persuasion for a counterattitudinal advocacy if the arguments were sufficiently compelling. This suggests that it is not the direction of the advocacy (proattitudinal or counterattitudinal) that is important, but rather the nature of the cognitive responses elicited.

Of course it is likely that proattitudinal advocacies will generally elicit favorable thoughts, whereas counterattitudinal advocacies will elicit primarily counterarguments, but this will not always be the case. Recent research has demonstrated the feasibility of constructing communications that take proattitudinal positions but employ arguments that elicit primarily counterarguments, and messages that take counterattitudinal positions but elicit primarily favorable thoughts (cf. Petty et al., 1976). The latter was also accomplished in the present investigation and allowed a strong empirical test of the hypothesis of interest.

It is also important to note that the attitudinal effects of issue involvement do not appear to be mediated by enhancing recall of the message arguments. Although high involvement did tend to increase argument recall for both the strong and weak messages in Experiment 2, high involvement increased persuasion for the strong message but decreased persuasion for the weak one. Also, consistent with previous research (e.g., Cacioppo & Petty, 1979; Insko, Lind, & LaTour, 1976; etc.), the within-cell correlations failed to substantiate a relationship between learning and persuasion.

The most compelling explanation for the present data appears to be that increased involvement enhances the importance of message content in producing persuasion. If the message content elicits primarily counterarguments, then increased involvement will tend to enhance the production of thoughts unfavorable to the advocacy and will result in decreased agreement; but if the message content elicits primarily favorable cognitions,

[2] Similar within-cell correlations among attitudes and cognitive responses were available for Experiment 1. The only significant correlation (based on an N of only 12) was between favorable thoughts and attitudes within the high involvement groups ($r = .58$, $p < .05$). Message recall was not assessed in the first study.

then involvement will tend to enhance these positive thoughts and will result in increased agreement. The correlational data from Experiment 2 further corroborated the view that increased involvement enhances the importance of message-based cognitions in producing persuasion. The correlations between attitudes and cognitive responses were substantially greater under high than under low involvement conditions.

The finding that increased involvement enhances the importance of message factors in producing persuasion may explain the previously confusing finding that sources of high and low credibility produce differential persuasion under low but not under high involvement conditions (e.g., Johnson & Scileppi, 1969; Rhine & Severance, 1970). The present analysis suggests that nonmessage cues such as the expertise or attractiveness of a source should have maximal impact when persuasion is not tied to an extensive processing of the message content, as when a message is on a topic of low involvement. On the other hand, characteristics of the message content should have maximal impact under high involvement conditions. This analysis suggests that low involvement persuasion situations may be governed by what cognitive psychologists have called "automatic processing," whereas high involvement persuasion situations may be governed more by "controlled processing" (Atkinson & Shiffrin, 1968; LaBerge, 1975; Schneider & Shiffrin, 1977; Shiffrin & Schneider, 1977). Under the former situations, message acceptance would be determined more by a well-practiced script such as "Experts are to be believed" (cf. Abelson, 1976; Langer, 1978), whereas under the latter situations message acceptance would be determined more by a subject's attention to and processing of the message content. In support of this conjecture, Chaiken (Note 1) reported that subjects were more affected by the number of arguments employed in a message under high than under low involvement conditions but were more affected by source attractiveness under low than under high involvement conditions.

At least two important questions about involvement remain unaddressed by the present research. One concerns *why* increased involvement should facilitate information processing. A possible explanation may reside in recent research indicating that information with self-relevance is processed more quickly than non-self-relevant information. For example, Markus (1977) argued that subjects have a more extensively developed "schema" or cognitive structure for self-relevant information and that this schema facilitates processing.

Another important question concerns the limitations on increased issue involvement facilitating processing. We suspect that there are circumstances where involvement may be so high, as when an issue is intimately associated with certain central values (cf. Ostrom & Brock, 1968), that processing will terminate in the interest of self-protection. This level of involvement was not reached in the present investigation, even though the message advocated a change in university policy that, if implemented, might have prevented many students from obtaining their degrees. Thus, within a normal range of involvement, increased issue importance appears to be associated with increased message processing. This enhanced processing will most likely lead to reduced persuasion when a message presents weak arguments (i.e., arguments that are open to refutation and counterargumentation), and to enhanced persuasion when a message presents particularly good arguments for which subjects have no readily available counterarguments (and thus favorable thoughts will predominate).

Toward a Viable Theory of Individual Differences

Joseph R. Royce
Center for Advanced Study in Theoretical Psychology
University of Alberta, Edmonton, Canada

This article deals with two metatheoretic issues: (a) the problem of making scientific inferences and (b) the problem of the conceptual framework. Inability to overcome inductive uncertainty lies at the core of the debates concerning the interpretation of factors and how they are organized. Failure to embed factors in a viable, process-oriented conceptual framework has also obstructed progress. Theoretical structures based on the information-processing paradigm and invariant factors are the most promising extant approaches.

This article is focused on conceptual issues rather than data. In particular, I am concerned with how we can best evolve a viable theory of individual differences (Royce, 1973a,b, 1978; Royce & Powell, Notes 1, 2). Theoretical analysis and synthesis *inevitably* involve metatheoretic issues as well as substantive issues (Royce, 1976). This interplay between metatheory and substantive theory is, of course, well recognized in advanced scientific domains and in philosophy of science. The message from these quarters is clear—Progress in developing substantive theory frequently requires clarification of underlying metatheoretic issues. Two such issues are central to this article: (a) the problem of scientific inference and (b) the problem of the conceptual framework.

The Problem of Scientific Inference

The argument is that factor analysis is as subject to the vagaries of inference as any other empiricoinductive scientific method. This means it is logically impossible to be *certain* about the interpretation of a factor (i.e., scientific inference involves inductive leaps.)[1] Thus, a major point that emerges is that the problem of scientific inference is not unique to factor methodology—It poses difficulties for all scientists, and for the philosophers of science as well (Hanson, 1961; Morgan, 1973; Popper, 1959, 1963; Rozeboom, 1961). However, it does *not* follow that factor methodology has a fatal disease and must therefore be buried. Rather, what is called for is that we spell out the implications of this and other metatheoretic issues in the service of advancing substantive theory.

While it has long been recognized that differential psychology might provide the key to our understanding of personality, the Achilles' heel of this approach has been the problem of identifying the fundamental dimensions of individuality. And although factor analysis as the best available scientific method for identifying the dimensions of organized complexity has reduced the number of required personality constructs from thousands to hundreds, the current state of the art is such that there is no mechanical algorithm available for deciding which dimensions are invariant. This means it is necessary to make qualitative judgments concerning this issue. It is my view that *the problem of factor invariance under-*

This article is a product of the Individuality Project, which is supported by Canada Council Grant Number S76-0908-R1.

lies the substantive conflicts and confusions concerning factors and their organization.

Contrary to common belief, there are two categories of factor invariance rather than one. These have been labeled *internal* and *external* invariance (Royce, 1976). Invariance of the first kind involves the replication of factors via several analyses despite differences in subjects, variables, and occasions. This constitutes the standard attack on the problem, which although essentially qualitative in nature, is nevertheless an effective and plausible procedure. For example, in high intensity domains of investigation, such as pilot aptitude (e.g., see the research of the U.S. Air Force Aviation Psychology Program, both the 19 volumes from World War II and the postwar reports) or rodent emotionality (Royce, 1977b), "marker variables" are so well-known that they constitute reliable and valid indices for specifiable factors.

External invariance refers to the empirical and/or laboratory manipulation of previously identified factors. The most extensive research programs devoted to experimental manipulation of factors include Fleishman's (1967) analyses of the learning dynamics of psychomotor dimensions, Eysenck's (1967) massive laboratory investigations of his three third-order constructs, and Royce's (1966, 1973a; Aftanas & Royce, 1969; Mos, Lukaweski, & Royce, 1977; Royce, Holmes, & Poley, 1975; Royce & Poley, 1973; Royce, Poley, & Yeudall, 1973; Royce, Yeudall, & Bock, 1976) identification of the genetic and brain site correlates of affective and cognitive factors. Although the call for combining multivariate and experimental method and thought was sounded some time ago (e.g., Cattell, 1966a, 1966b; Cronbach, 1957; Royce, 1950), it is unfortunately true that the volume of output that combines the two modes of attack is relatively small. The best single exemplar of this research paradigm is still embodied in the Cattell (1966a) handbook. But the Society of Multivariate Experimental Psychology journal *Multivariate Behavioral Research* has not been very effective in this bridging role (e.g., see Royce, 1977a), despite the hopes of the founding fathers (Cattell, 1966b). Multivariate experimental research is very demanding, both in terms of orchestrating the relevant skills and in funding, so it will probably be some time before it hits full stride. Let me briefly cite two examples in order to make this point plainer. First example: There are no longitudinal data available as an empirical basis for a multivariate developmental psychology. The available theoretical models (e.g., Kearsley, Buss, & Royce, 1977) are based on extrapolations to the life span from cross-sectional data. Large-scale testing of an appropriate sample of subjects and factors throughout the life span can only be accomplished by establishing a massive research institute that can outlive its investigators. Second example: There is no large-scale research program devoted to identifying the brain correlates of factors. There have been sporadic factorial studies of humans with brain damage, but there has been no sustained experimental attack on the problem of the brain correlates of factors. Such a program would require experimental lesioning, microelectrode implantations, and other brain intervention techniques on appropriate animal populations (e.g., subhuman primates in the case of cognitive factors), in addition to a sophisticated and sustained factor strategy. Proper implementation of such a research program would require an interdisciplinary team that would range across factor analysis, psychometrics, animal behavior, and neuropsychology. It would also require access to a large number of humans with a broad range of brain damage and extensive laboratory and animal facilities as well, so that a variety of biological manipulations of psychological factors could be carried out. These examples bring out the cost factor on the one hand and the potential value of such investigations on the other hand. I cite these examples in order to emphasize the point that we need both internal and external invariance strategies in order to establish the "boundary conditions" (e.g., Factor A is functional at the early stages of learning a complex motor task, but nonfunctional during the later stages) or the range of effectiveness for each factorially identified unknown.

Although the intent of efforts to find a mathematical solution to the invariance prob-

em is to generate invariant factors algorithmically, this may not be possible in principle (for example, because of an insufficiency of information concerning the factors under comparison). This means that the present state of the art is such that subjective judgments regarding the interpretation and invariance of factors cannot be avoided. Thus, the hypothesis-generating character of factor theory must be taken seriously—that is, the interpretation that Factor x is concerned with x and not x' or y is a tentative hypothesis. However, the principle of *empirical tenability* says that as factor investigators increase their knowledge of the "boundary conditions" of factors, these empirical constraints will increase the probability that the nth interpretation of Factor x is a more *plausible hypothesis* (Royce, 1976).

Problems of factor invariance are compounded by methodological difficulties and a relative paucity of data when we move on to higher order factors. For example, there are ambiguities concerning causal influences between levels, there are problems concerning the partitioning of the common factor variance between levels, and there are ambiguities concerning the conceptual status of higher strata factors (e.g., see Cattell, 1965a, for the best available treatment of these issues). But despite these methodological difficulties, all factor analysts share the same goal—namely, to identify invariant factors, to specify how they are organized, and to specify how factors function as parts of complex behaviors. Thus we must transcend methodological and other shortcomings in pursuit of these common goals (e.g., via such requirements as factor invariance), if we are to overcome the historical conflicts (exemplified once again in the current exchange between Guilford, 1975, 1977, and Eysenck, 1977) that have dominated this complex and important area of investigation.

The Problem of the Conceptual Framework

A critical implication of this problem is that the mere inventorying of invariant factors *cannot* generate advanced forms of science because explanatory theory requires viable conceptual frameworks on which to hang empirical observables (Royce, 1976, 1978). The point is that factor analysis per se is incapable of providing the prerequisite conceptual framework for its substantive findings. What it can do is identify potentially unifying components of such a framework (Royce, 1963), but the subsuming model (of which factors are critical parts) must come from elsewhere. This point has not been adequately perceived by either the factor analysts or their critics. The major shortcoming of the factor analytic proponents is their belief that a theoretical structure could somehow be automatically generated as a natural consequence of inventorying invariant factors. The major implication of this view is the belief that the factor model constitutes a sufficient framework on which to hang its substantive observables. Thus its major proponents, such as Guilford (1967) and Cattell (1965b, 1973), have tended to develop theoretical structures based primarily on the factor model. A major consequence of this conceptual commitment is that personality theory too heavily based on factor analysis has not been able to go beyond structure to dynamics.

While there have been occasional noises from within the factor subcommunity concerning the need to get at process (e.g., see Messick, 1973), it is the current interaction between the two sciences (i.e., multivariate and experimental psychology) that is forcing the issue of conceptual framework into such sharp focus. For it is the experimental tradition that has kept its eye on process. But it is the importation of a new ingredient, the information-processing paradigm, that is of particular importance in this context. For this new paradigm is the conceptual framework that is bringing multivariate and experimental psychology together in an effort to understand complex psychological phenomena. The most important empirical work in this vein is being conducted in the cognitive domain (Carroll, 1976, 1978; Hunt, 1974; Hunt, Frost, & Lunneborg, 1973; Snow, 1976a,b; and Sternberg, 1977). And the most explicit and comprehensive theoretical structure to combine the information-processing paradigm with the two psychologies is Royce's multifactor system theory of individual differences (see Royce &

Buss, 1976; Royce, Kearsley, & Klare, 1978; Royce & Powell, Note 1 and Note 2, for an overview). This theory defines personality as the total psychological unit, a suprasystem that is composed of six interacting systems. The cognitive (Diamond & Royce, in press; Powell & Royce, Note 3) and affective (Royce & McDermott, 1977) systems are conceptualized as processing units that function as information transformers. The style (Wardell & Royce, 1978) and value (Schopflocher, Royce, & Meehan, Note 4) systems are also central processing units, but they function more as personality integrators. Finally, the sensory (Kearsley & Royce, 1977) and motor (Powell, Katzko, & Royce, 1978) systems are more peripheral processing units that function as input/output transducers and encoders. These six systems are organized as a multilevel, hierarchical suprasystem (Mesarovic, Macko, & Takahara, 1970) in which there is a controlled-process stratum (sensory, motor), a learning–coping stratum (cognitive, affective), and an integrative stratum (style, value). In turn, each of the six systems is also conceptualized as a multilevel, hierarchical system, where the elements of the hierarchies are identified via factor analysis.

The long-range goal of factor research is to understand variations in psychological functioning. But this kind of understanding implies the availability of a viable theory, which in turn implies the availability of an appropriate conceptual framework. The most germane candidate is the information-processing paradigm. This paradigm has the potential of generating a viable, dynamic theory of individual differences.
